Since η is small the first solution gives non-relativistic motion, while the second gives ultrarelativistic motion. In the former case we can put $\gamma_1^2 \simeq 1 + v_1^2/c^2$. Thus to good approximation:

$$\frac{v_1}{c} = \frac{\alpha}{2n} = \frac{1}{274n} \tag{8a}$$

$$\gamma_2 = \frac{n}{\alpha} = 137n \tag{8b}$$

Using these results, the radii of the stationary orbits as obtained from equation (4) are:

$$r_{n_1} = \frac{n^2\hbar^2}{me^2} \tag{9a}$$

$$r_{n_2} = \frac{1}{2}\left(\frac{e^2}{mc^2}\right)\frac{n/\alpha}{(n^2/\alpha^2 - 1)^{1/2}} \simeq \frac{e^2}{2mc^2} \tag{9b}$$

Formula (9a), with $n = 1$, gives the radius of the first Bohr orbit of the hydrogen atom, a_0. The electron and positron are therefore separated by $2a_0$. If we had adopted the rest frame of the positron rather than the centre of mass frame we should have obtained the same result by

introducing a reduced mass, $m^* = \frac{1}{2}m$. Thus, the first solution yields the ordinary non-relativistic states of positronium with which we are already familiar.

The second solution, however, gives something quite new. The stationary orbits all have radii very close to $\frac{1}{2}r_0$, where $r_0 = e^2/mc^2 = 2{\cdot}818 \times 10^{-13}$ cm. The particles are therefore separated by r_0. The constant r_0 is sometimes known as the classical electron radius, but this significance must not be taken literally. In fact, there has recently been a return to the old view that the mass of the electron is purely electromagnetic, in both classical[5] and quantum theories[6,7]. Rohrlich[8] has shown that the energy and momentum in the field of the classical electron form the 4-vector, $-\int T^{\alpha\beta}v_\beta d\tau_0$, where $d\tau_0$ is an invariant 3-volume element; this removes an old difficulty.

The energy states for the second (relativistic) solution are:

$$E_n = 2\gamma_n mc^2 - \frac{\gamma_n e^2}{4r_n}\left(1 + \frac{v_n{}^2}{c^2}\right) \qquad (10)$$

$$\simeq \gamma_n mc^2$$

$$\simeq 137nmc^2$$

where equation (3), with $v \simeq c$, has been used, and γ_n has been obtained from equation (8*b*).

Sternglass[9] was the first to obtain relativistic positronium states of this type. However, his force law appears to be in error because he does not work out the centrifugal force in an inertial frame before transforming to the rest frame of the positron, and also because he introduces the Thomas precession as an "extra" when quantizing angular momentum, not realizing that this precession is already implied by relativistic equations. His stationary energy states have twice the value (10). Schild[10] has taken advantage of the time-symmetry of the fields in deriving a force law from a Fokker or Wheeler–Feynman action principle, in which the field variables do not appear. He fails to obtain the relativistic energy states for reasons that are not immediately apparent. We may note, however, that the relativistic energy states would disappear from our analysis also, if the $+v^2/c^2$ term of the force law (2) were replaced by a $-v^2/c^2$ term (this would be wrong because the instantaneous velocities of the electron and positron are opposite).

With the value of γ_2 given by equation (8*b*) for $n = 1$, the interaction potential energy of the electron and positron becomes:

$$V = \frac{137e^2}{4r}\left(1 + \frac{v^2}{c^2}\right) = \frac{\hbar c}{2r_0}\left(1 + \frac{v^2}{c^2}\right) \simeq \frac{\hbar c}{r_0} \qquad (11)$$

The rotation of the electron constitutes a current, $e/c\tau$, where $\tau = \pi r_0/v$. The orbital magnetic moment ($\pi r_0^2/4$ times this current) is therefore $er_0/4$ since $v \simeq c$. The spin magnetic moment of the electron is $(e/mc)\frac{1}{2}\hbar$. If μ_0 and μ_s denote the orbital and spin magnetic moments, respectively, we have for the interaction energy of these dipole moments the formula:

$$V^1 = \frac{\mu_0\mu_s}{r^3} = \frac{8\mu_0\mu_s}{r_0{}^3} = \frac{c\hbar}{r_0} \qquad (12)$$

This has the same magnitude as our relativistic interaction potential energy (11). Thus the coupling given by the force law (2) in the relativistic limit is of the form $(\text{spin})_1$–$(\text{orbit})_2$, where the suffixes 1 and 2 denote the two particles. It would appear that forces of the same order as strong nuclear forces can be obtained from relativistic electrodynamics. All nuclear forces may be electrodynamic in nature.

To return to the significance of our new energy states (10), it will be noted that the energies are positive. This is in contrast with the non-relativistic case where the positive energy states are continuous. Evidently each of the two leptons (we restrict this term to refer to an electron or positron, and later we shall include a neutrino or antineutrino) contributes $\frac{1}{2}(137)mc^2$ to the ground state energy of the relativistic positronium system. This system probably decays too rapidly to be observed as a fundamental particle. However, in view of the magnetic character of the coupling, it is not unreasonable to postulate that a relativistic system containing N leptons would have rest energy close to $\frac{1}{2}N(137)mc^2$. It is a curious and hitherto unexplained fact that the rest energies of the mesons are indeed close to integral multiples of $\frac{1}{2}(137)mc^2$. This empirical law has been known for some time[11–13]. In Table 1 the rest masses predicted by the empirical law and the observed rest masses are compared. The muon would contain 3 leptons, the pion 4, the kaon 14 and the proton 27 (for the more massive particles accumulated corrections will become significant). The π^0 has a rest energy which is $9mc^2$ less than that of π^+ or π^- and about $10mc^2$ less than predicted. The π^0 consists of two relativistic positronium units which may be coupled by this energy. The η meson, a resonance particle with a rest mass of 1072·0 (expressed in units of mc^2), could be regarded as built up from $\pi^+ + \pi^- + \pi^0 + \pi^0$, which yields a total rest mass of 1074·8.

Table 1. PREDICTED AND OBSERVED REST MASSES

Particle	Spin	N	$\frac{1}{2}(137)N$	Observed mass (mc^2)
μ^+, μ^-	$\frac{1}{2}$	3	205 5	206·8
π^0	0	4	274·0	264 2
π^+, π^-	0	4	274 0	273·2
κ^0	0	14	959·0	974·5
κ^+, κ^-	0	14	959·0	966 8
ϱ	1	27	1,849·0	1,836·0

If the spin vectors of the leptons within a composite particle are aligned parallel, the resultant spin will be half-integral or integral depending on whether the number of leptons is odd or even. The spins of the composite particles do indeed appear to obey this rule (Table 1).

In the case of the muons charge is conserved. We can say that the μ^+ consists of two positrons and an electron, the μ^- two electrons and a positron. No neutral muon has been discovered. The neutral pion also presents no problem since it consists of two electrons and two positrons, and not unexpectedly decays into two photons. The charged pions, however, present a difficulty if charge is conserved. On the grounds that each constituent lepton contributes $\frac{1}{2}(137)mc^2$ to the rest energy we have assigned four leptons to the charged pion, and this is consistent with its spin of zero. One of the leptons, while making the standard contribution to the rest energy, does not apparently contribute to the charge. Could this particle be a neutrino, for which we have as yet found no role? But how is a neutral particle able to interact magnetically with electrons and positrons?

Perhaps the answer is that the charged pions are excited states of the muons, and therefore contain only three charged leptons. The distinction between the first excited state of a three-lepton system and the ground state of a four-lepton system may be without significance. For example, rather than describe the π^0 as two positronium units we might, in accordance with equation (10), regard it as the first excited state of a single positronium unit. The neutrino would then acquire a significance like that of the photon—it would be a means of carrying away a half-integral quantum of angular momentum. In the decay of the muon, $\mu^\pm \rightarrow e^\pm + \nu + \emptyset$, we see that an electron pair may annihilate into a neutrino pair.

If helium ions are bombarded with electrons, it is found that the capture cross-section is greatest at certain kinetic energies. These resonances occur when the kinetic energy plus the ionization potential for the level into which the electron is captured are just sufficient to excite the electron in the ground state of the helium ion into a discrete level, resulting in a doubly excited state which we shall denote by He'' (ref. 14). The reverse process is the autoionization of He'', namely, $He'' \rightarrow He^+ + e^-$, and is known to occur in times of order 10^{-12} to 10^{-13} sec. It is now possible to create doubly excited states directly from helium by absorption of radiation in the vacuum ultra-violet[15]. We wish to point out the strong analogy

between the autoionization of He″ and a fundamental particle decay. In the case of the autoionization, the energy available to liberate one electron comes from the fall of the other electron from an excited level to the ground level and is discrete. Hence the electron is liberated with a preferred kinetic energy. By analysing the kinetic energies of the decay products of certain fundamental particles analogues of He″, termed resonance particles, have been discovered.

The short lifetime of the resonance particles (10^{-23} sec) indicates that they decay by allowed transitions. The longer-lived mesons, with lifetimes of the order of 10^{-10} sec, are really metastable states, the decay of which must proceed by a forbidden transition. The spontaneous decay of fundamental particles is possible because their energies are positive.

We would argue, therefore, that all matter is built up from electrons and positrons, in accordance with a previous suggestion[16]. Only electromagnetic and gravitational fields will exist in Nature. If the mass of the electron is purely electromagnetic, then the energy in the electromagnetic field will be the source of the gravitational field, and the neutrino (as described here) will become the elementary particle of the gravitational field.

If all matter is built up from electrons and positrons, one has to explain the absence of antimatter. Gray[17] has suggested that the conservation of parity in chemical syntheses may have an analogue in the evolution of a universe of particular parity from an initial chance asymmetry.

RADIAL SPREAD OF A LIQUID STREAM ON A HORIZONTAL PLATE

By R. G. OLSSON and E. T. TURKDOGAN

Edgar C. Bain Laboratory for Fundamental Research, United States Steel Corporation, Research Center, Monroeville, Pennsylvania

IT is a common observation, seen, for example, in a kitchen sink, that a stream of liquid falling vertically on to a horizontal plate spreads out radially in a particular manner. Around the point of impingement there is a circular zone in which a thin layer of liquid moves radially with a high velocity. At the edge of this region the liquid layer abruptly becomes much thicker and consequently flows radially at a much lower velocity. This transformation is called the "hydraulic jump". This article deals primarily with the region inside the jump.

Recently, in one of the very few papers on this subject, Watson[1] applied the boundary layer theory to the analysis of flow inside the jump. The flow is characterized by a boundary layer that begins at the stagnation point and increases in thickness with radial spread. The expenditure of energy due to the creation of new surface was not considered. The fluid velocity outside the boundary layer was considered to remain almost constant and essentially equal to the falling stream velocity, U_0. By assuming a Blasius flat-plate profile for the velocity distribution, Watson obtained an approximate solution of the boundary layer equation in the usual manner.

Beyond a certain radial distance $r > r_0$, the viscous stresses are taken to affect the free surface such that the whole flow is considered to be of boundary layer type. Therefore, for distance $r > r_0$, the surface velocity decreases with increasing radial distance.

According to Watson's analysis, the merging of the boundary layer and the surface takes place at $(r_0/a)R^{-1/3} = 0{\cdot}3155$, where Reynolds number $R = Q/\nu a$ (Q being the volume flow rate of the falling stream, ν its kinematic viscosity, and a its radius). Although some experiments were carried out by Watson on the spread of a falling stream on a horizontal plate, his results do not prove or disprove the applicability of the theoretical analysis given.

In the present investigation several experiments were conducted to provide insight into the nature of the region within the jump and speculations are made concerning the applicability of simple theoretical analysis to the hydrodynamics of this system.

The falling streams were generally formed at an orifice in the base of a constant head calming tank. The head of the liquid in the tank was 9·9 cm or 18·3 cm, and the free-fall height of the jet to impact was 10·2 cm. The volumetric flow-rate of the liquid was varied from 9 to 111 cm³/sec by varying the orifice radius from 0·16 to 0·40 cm. The experiments were carried out using different liquids, for example, methylene bromide, water or water–glycerine solution, such that the kinematic viscosity could be varied from 0·004 to 0·052 cm²/sec. The stream diameters at the deflexion plate were calculated.

The impingement of water from a conventional tap on a plate was also observed. By careful adjustment of the tap, a relatively smooth stream of water could be obtained. The diameter of the stream was measured with callipers close to the surface of the deflexion plate. The volumetric flow-rate in these experiments was varied from 41 to 182 cm³/sec.

In the first series of experiments, an attempt was made to determine the kinetic energy of the liquid inside the jump as a function of radial distance. The jet was directed to the centre of horizontal disks having diameters such that the liquid flies from the edge, forming an "umbrella". If surface tension effects were negligible, the profile of the umbrella would clearly be parabolic with apex at the edge of the disk (like a ball or projectile launched horizontally). However, it was observed that this profile was decidedly not parabolic. This marked departure is shown in Fig. 1. In all cases the initial slope of the profile is definitely not zero, and furthermore, actual contraction of the umbrella occurs for sufficiently great fall. Clearly surface tension plays a marked part.

In the second series of experiments, the thickness of the liquid layer inside and outside the hydraulic jump was measured as a function of radial position for a number of jets, using different liquids. In these experiments the stream was directed normally on to the surface of a large

glass plate and depth measurements were made with a vernier height gauge having a needle pointer.

Some of the results obtained on thickness profiles using different liquid streams are given in Fig. 2. The curve drawn by dotted lines for a particular case is calculated film thickness, h, for inviscid flow, that is, $h = a^2/2r$. The observed difference between the measured film thickness and those computed for inviscid flow manifests the viscous flow effect within this region. Depending on the Reynolds number of the falling stream and the kind of liquid used, the average film thickness inside the jump was within the range 0·01–0·09 cm, and after hydraulic jump, the thickness increased to 0·1–0·3 cm. Outside the jump little or no variation in film thickness was noted with increasing radial distance.

Several high-speed motion pictures (2,000 frames/sec) were taken of various falling liquid streams spreading radially on a horizontal plate. The high-speed photographs in Figs. 3 and 4 are examples showing the appearance of the falling stream and of the radial flow for water and a water–glycerine solution. Because of the low kinematic viscosity of water, that is, $\nu \simeq 0{\cdot}01$ cm²/sec, the stream (Fig. 3) is rough and consequently is responsible for the formation of ripples on the surface of the region inside the jump. The height of these ripples could not be measured with any degree of accuracy; furthermore, as seen from the photograph in Fig. 3, the ripples interfere

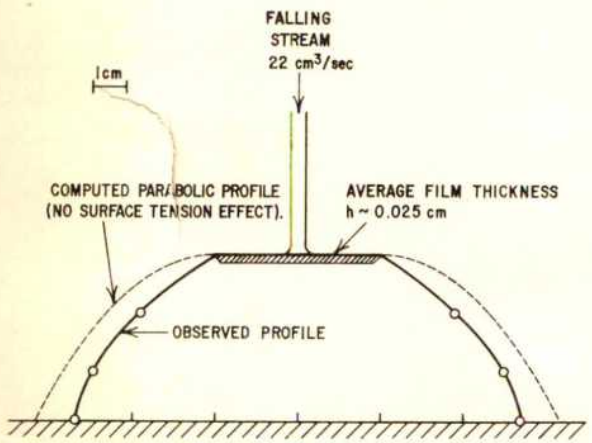

Fig. 1. Experimental umbrella profile for a methylene bromide stream impinging on a small disk

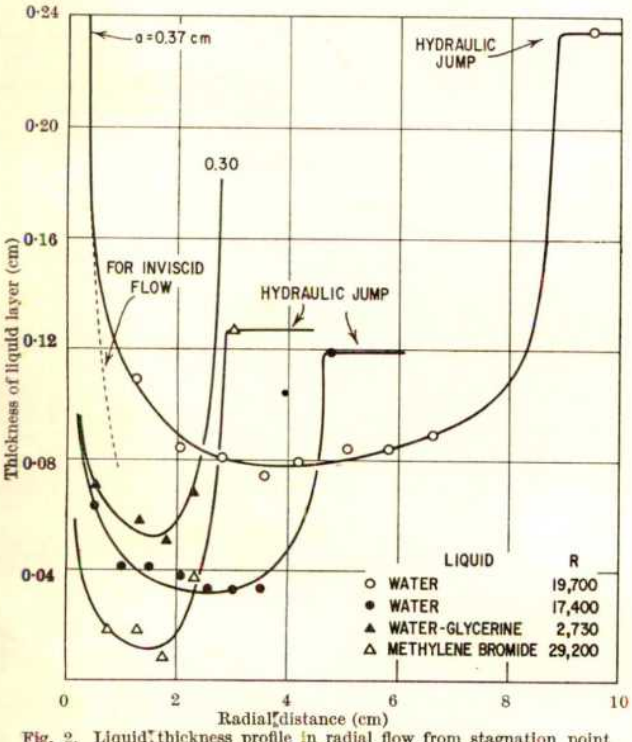

Fig. 2. Liquid thickness profile in radial flow from stagnation point using different liquids

Fig. 3. High-speed photograph (1/2,000 sec) of radial flow of water stream impinging on a horizontal plate. R = 14,800, a = 0·25 cm, rj = 5·3 cm

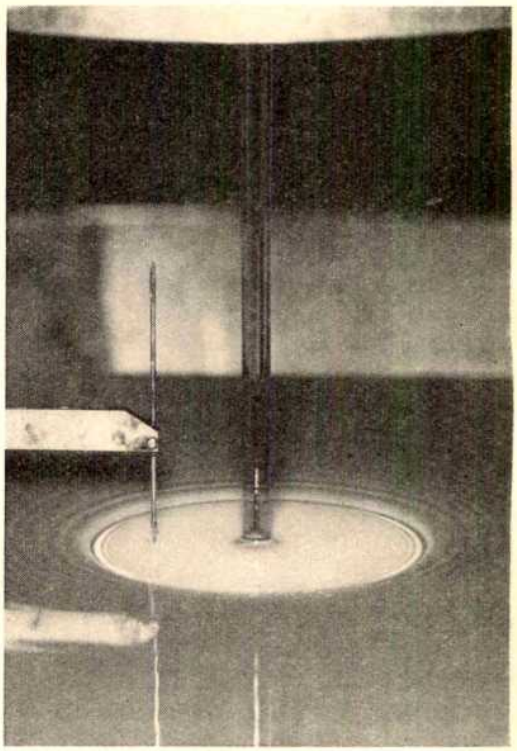

Fig. 4. High-speed photograph (1/2,000 sec) of radial flow of water-glycerine solution stream impinging on a horizontal plate. R = 2,730, a = 0·24 cm, rj = 2·8 cm

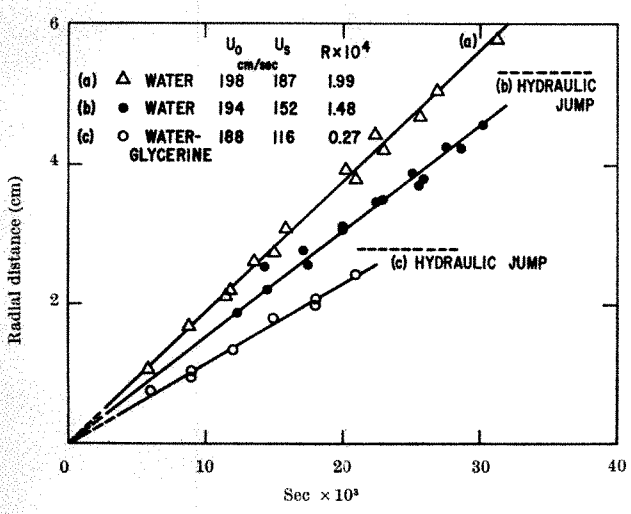

Fig. 5. Surface velocity, U_s, of the liquid inside the jump using water and water–glycerine solution

to some extent with measurements of film thickness. In the case of water–glycerine (Fig. 4), having $\nu = 0{\cdot}05$ cm²/sec, both the stream and the radial flow are very smooth.

When high-speed motion pictures were taken, very small pieces of cork were dropped on to the region within the jump and were used to measure the surface velocity of radial flow. As can be seen from the examples given in Fig. 5, the surface velocity remains essentially constant almost up to the position of the hydraulic jump, for which $(r_j/a)\ R^{-1/3}$ is between 0·84–0·89 for the examples considered. That is, according to the present experimental work, the boundary layer does not extend to the surface at $(r/a)\ R^{-1/3} = 0{\cdot}3155$ as derived by Watson from the application of the boundary layer theory but at a much greater radial distance, if at all.

It should also be mentioned that the surface velocity estimated from the rate of propagation of the ripples (Fig. 3) agrees reasonably well with those determined from the motion of cork particles on the surface of the liquid. The attempts to measure the surface velocity outside the jump have not been successful.

Another point of interest is that although the surface velocity, U_s, inside the jump remains constant, it is decidedly less than the velocity of the falling stream, U_0. However, the indications are that the ratio U_s/U_0 approaches unity with increasing Reynolds number of the falling stream. The significance of this observation is not clear at present.

The experimental data have given some indication of the complexity of the system under investigation. It is clear that even an approximate solution of the Navier–Stokes equation for the radial flow considered becomes a very complex mathematical problem.

Under these circumstances, all that can be done is to look for some empirical correlation which may summarize the data in a more condensed form. As an example, Fig. 6 shows the variation of the jump radius r_j as a function of Reynolds number for various liquids. In order to obtain a meaningful correlation for several liquids together, surface tension effects would also have to be considered. Since the present experiments were conducted over a narrow range of surface tensions, no such correlation was attempted.

The decrease in the magnitude of the liquid stream momentum brought about by the radial spread can be estimated from the height, h, and radius of the hydraulic jump. The momentum flux of the falling stream is $\rho Q U_0 (= \rho Q^2/\pi a^2)$. If it is assumed that the velocity profile of the thick, relatively slow-moving region beyond the hydraulic jump is fairly flat, the momentum flux just beyond the jump is $\rho Q U_j (= \rho Q^2/2\pi r_j d_j)$. Consequently, the ratio of their magnitudes is given by:

$$\frac{\text{momentum flux after jump}}{\text{momentum flux of falling stream}} = \frac{a^2}{2r_j d}$$

which is found in the present experiments to be within the range 0·02–0·04

The momentum flux just before the jump is obtained by adding the momentum flux required to maintain the standing wave to the momentum flux just beyond the jump. This gives:

$$\rho Q^2/2\pi r_j d_j + \pi r_j \rho g\ (d^2 - h^2)$$

where h is the film thickness just before the jump and g is the gravitational constant. Since h is small compared with d, the ratio of magnitudes is given by:

$$\frac{\text{momentum flux before jump}}{\text{momentum flux of falling stream}} = \frac{Q^2/2\pi r_j d_j + \pi r_j g d^2}{Q^2/\pi a^2}$$

In all the experiments carried out, this ratio was found to be within the range 0·07–0·16.

Observed variations in these ratios could not be correlated as a function of independent variables of the falling stream.

The corresponding ratios of kinetic energy are obtained by squaring the momentum ratios. The kinetic energy ratio is quite small before the jump and effectively zero after the jump.

It is possible to estimate the portion of kinetic energy loss brought about by expansion of the surface. For the expansion to the jump radius the rate of loss of kinetic energy due to the surface tension effect at the free surface is given by:

$$\frac{dE}{dt} = 2\pi r_j U_s \gamma$$

where γ is the surface tension of the liquid. The kinetic energy of the falling stream is equal to $1/2\ \rho Q U_0^2$. Since the kinetic energy of the stream is almost entirely lost at the jump, the fraction of kinetic energy loss due to surface expansion is given by:

$$\frac{4\pi r_j \gamma U_s}{\rho Q U_0^2}$$

In the several experiments in which surface velocity was measured, this ratio for water was about 50 per cent and for the water–glycerine solution about 20 per cent. The remaining kinetic energy losses are primarily due to viscous effects.

It is to be expected that an increase in viscosity (with all other things remaining the same) will result in a greater loss of energy due to viscous effects per unit area. Since the kinetic energy available is limited, this will result in

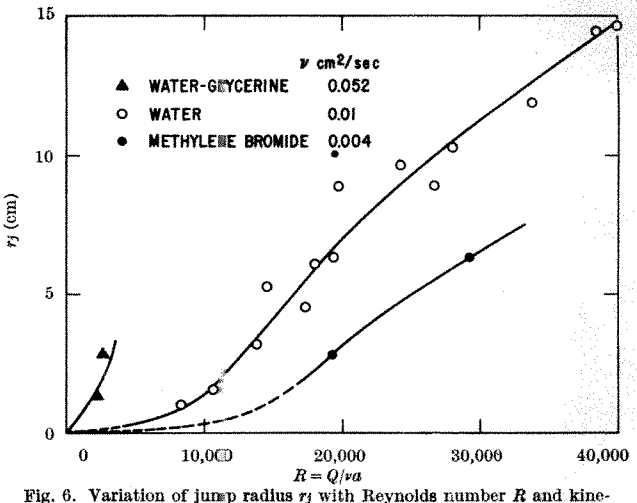

Fig. 6. Variation of jump radius r_j with Reynolds number R and kinematic viscosity of liquid

a smaller hydraulic radius and consequently a smaller share of the kinetic energy loss caused by surface expansion.

Since most of the kinetic energy of the stream is lost at the jump, further expansion of the surface beyond the jump will be slight. As a result, the product rU_s in this region will tend to be constant. If it is again assumed that the velocity profile remains fairly flat throughout this region (for example, $U = \frac{Q}{2\pi rd}$), it can be seen that the liquid thickness, d, also tends to remain constant for a given case.

The thickness d of the liquid layer can be increased, as desired, by placing a ledge around the splash plate. An increase in d will, of course, reduce the jump diameter. Beyond a critical value of d, the hydraulic jump will disappear completely.

Summary

As a falling liquid stream spreads radially on a horizontal plate, the surface velocity of the region within the jump remains essentially constant almost up to the position of the hydraulic jump. It is found experimentally that the ratio of the surface velocity to the initial velocity increases from 0·6 to 0·94 as the Reynolds number for the stream increases from about 3,000 to 20,000. The kinetic energy of the falling stream is essentially completely dissipated at the hydraulic jump. The fraction of kinetic energy expended in the creation of new surface is shown to be quite large.

TERNARY AND QUATERNARY AQUEOUS SYSTEMS CONTAINING BILE SALT, LECITHIN, AND CHOLESTEROL

By DONALD M. SMALL*, MARTINE BOURGÈS and D. G. DERVICHIAN

Service de Biophysique, Institut Pasteur, Paris

THE solubilization in aqueous phases of insoluble amphiphilic substances by association with more soluble similar substances is of interest, not only from a purely physicochemical point of view but also because of its industrial (detergents) and biological applications.

The particular problem to be discussed here concerns the solubilization of phospholipids and cholesterol in biological fluids—particularly bile. About six hundred mixtures representing all possible proportions of bile salt, lecithin, cholesterol, and water were prepared and examined with a polarizing microscope and 250 of these analysed by X-ray diffraction. Pure sodium cholate was used as the bile salt (solubility in water at 20° C = 56 per cent). Cholesterol recrystallized four times from hot methanol (final melting-point 148° C was used), and the pure egg lecithin was prepared in this laboratory[1]. In order to maintain the *p*H of the mixtures greater than 8 (at which there is almost no free bile acid), the distilled water used was brought to *p*H 10 with sodium hydroxide and stored under nitrogen. All experiments were carried out in the region of 22°–24° C.

Bile salt is very soluble in water, but cholesterol is almost totally insoluble. Lecithin is not soluble in water but swells to form a paracrystalline phase. Even in very large volumes of water lecithin simply forms a dispersion of the swollen phase[2].

* Present address: c/o The Department of Medicine, Boston University, Medical Center, Boston, Massachusetts.

Ternary Systems. Before examining the quaternary system, the three ternary systems: (*a*) bile salt–cholesterol–water, (*b*) lecithin–cholesterol–water, and (*c*) bile salt–lecithin–water, were investigated. Ternary phase diagrams representing these systems are presented in Fig. 1. It can be seen from Fig. 1*a* that the ability of sodium cholate to solubilize cholesterol is very weak: the quantity of cholesterol solubilized in water represents at the most 2 per cent of the weight of sodium cholate present, regardless of the quantity of water. All mixtures with more than 2 per cent cholesterol, or more than 56 per cent sodium cholate (as a percentage of weight of all three components), form either two or three phases. The phases are: (1) the isotropic solution containing 2 per cent or less cholesterol solubilized by the bile salt; (2) the crystals of sodium cholate; (3) the crystals of cholesterol. However, it can be seen in Fig. 1*b* that up to 33 per cent cholesterol (which corresponds to a molecular ratio with lecithin of 1 : 1) can be incorporated in a paracrystalline phase given by lecithin and water. This system, however, never forms an isotropic micellar solution.

The system bile salt–lecithin–water is of some interest as it gives three paracrystalline phases labelled I, II and III in Fig. 1*c* and an isotropic solution (phase IV). Phase I is analogous to the "neat soap" of the aqueous soap systems. All the mixtures with compositions falling into this area show a lamellar structure with the long spacings (D) ranging from 38 Å to 75 Å according to

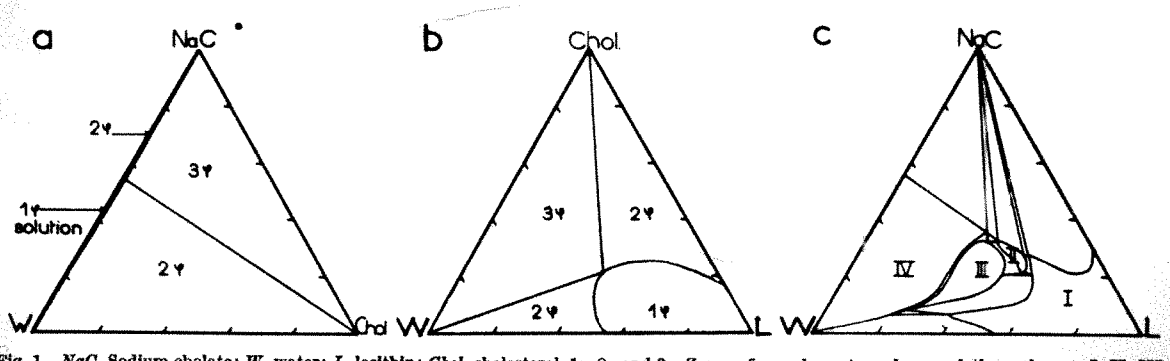

Fig. 1. *NaC*, Sodium cholate; *W*, water; *L*, lecithin; *Chol*, cholesterol. 1φ, 2φ and 3φ, Zones of one phase, two phase and three phases. I, II, III : paracrystalline phases (see text); IV : isotropic solution (see text)

the composition. From the measured long spacings (D) and the quantity of water present the thickness (d_w) of the interstitial water layer and the thickness (d_L) of the lipid layer can be calculated. The thickness (d_w) of the water varies between the extreme values of 0 (anhydrous) and 34 Å. As for the lipid layer, its calculated thickness (d_L) depends not only on the amount of water present but also the amount of bile salt in the lipid layers. Thus, for example, the thickness (d_L) may fall from 42·5 Å to 33·5 Å with increasing hydration and, at a certain constant water concentration, d_L falls from 42 Å to 31 Å with increasing bile salt concentration. The calculated area per molecule in this layered structure varies from 70 Å² to 59 Å². These mean molecular areas correspond to those obtained with similar proportions of lecithin and cholic acid spread as monolayers and compressed to a pressure of 25–30 dynes/cm (ref. 3).

Phase II, although isotropic, is very thick, almost rigid and gives long spacings corresponding to a face-centred cubic lattice. This phase is probably made up of dodecahedrally deformed spherical micelles of lecithin and bile salt packed in a face-centred cubic lattice. It is analogous to the cubic phase described by Luzzati *et al.*[4] for certain soap and detergent systems. In this phase D ranges from 39 Å to 43·5 Å.

Phase III is analogous to the "middle soap" in aqueous soap systems and gives long spacings corresponding to hexagonally packed indefinitely long cylinders as described by Luzzati *et al.*[4] for the "middle soap". Depending on the proportions of the components, the axis to axis distance (D) between the cylinders ranges from 39·5 Å to 70 Å. The calculated diameter (d_L) of the lipid cylinders ranges from 32·5 Å to 49·5 Å. Either an increase in hydration or an increase in bile salt content of the cylinders produces a decrease in the diameter of the cylinders. The calculated water thickness between the adjacent cylinders ranges from 5 Å to 25 Å. The calculated area per molecule in this phase varies from 96 Å to 116 Å². These areas are the same as those found with similar proportions of lecithin–cholic acid mixtures spread as monolayers compressed to a pressure of 6 dynes/cm (ref. 3).

Phase IV is an isotropic micellar solution. This phase extends up to and includes a mixture containing nearly equal weights of the three components (36 per cent bile salt, 34 per cent lecithin and 30 per cent water). In order to gain some information about the micellar dispersion in this phase preliminary light-scattering measurements were performed on aqueous solutions containing 2 per cent sodium cholate and increasing amounts of lecithin. The micellar weight rises gradually from 1,650 for a 2 per cent sodium cholate solution to 16,500 for a solution containing about 3 per cent lecithin and 2 per cent sodium cholate. Further addition of lecithin up to 5 per cent effects a slight fall in micellar weight to 15,000.

The zones between these four different areas represent compositions which produce two coexisting phases or three phases of fixed composition. These phases can be crystalline (sodium cholate crystals), paracrystalline (I, II, III) or the isotropic solution (IV).

The effect of changing the nature of the bile salt should be emphasized here. The same series of systems was prepared, but this time a mixture of naturally occurring conjugated bile salts extracted from beef bile was substituted for the pure sodium cholate[1]. The diagram obtained was very similar, so far as the paracrystalline phases I, II, and III were concerned, when compared with the diagram obtained with pure sodium cholate. Even the lower limits of the isotropic phase (IV) were similar; the only difference was the disappearance of the upper linear frontier, which meant that an increasing amount of bile salt could be added without there being any separation into crystals. This is understandable when it is remembered that the mixture of naturally occurring bile salt is soluble in water in all proportions—contrary to pure sodium cholate the maximum solubility of which is 56 per cent.

The effect of substituting this conjugated bile salt mixture for sodium cholate in the bile salt–cholesterol–water system (Fig. 1*a*) was simply to extend the upper border of the solution from a point at 56 per cent bile

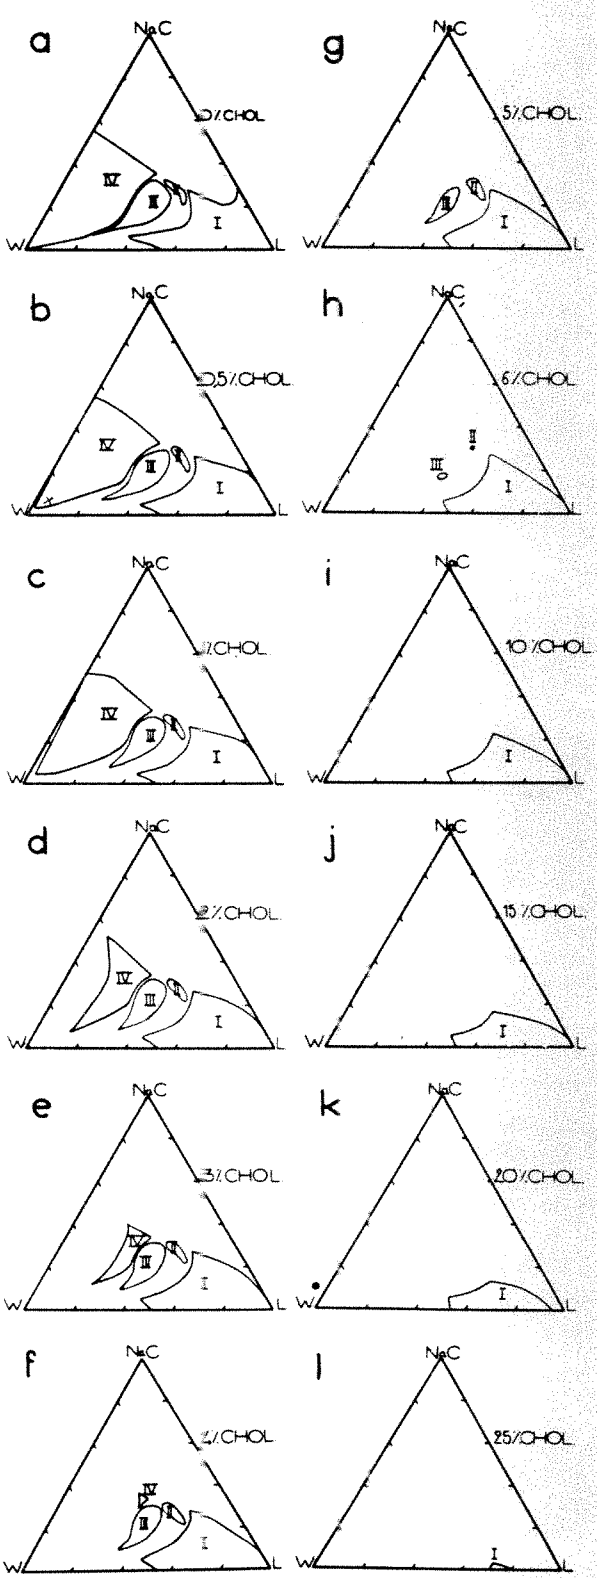

Fig. 2. *NaC*, Sodium cholate; *W*, water; *L*, lecithin; *Chol.*, cholesterol.
I, II, III paracrystalline phases } see text
IV: isotropic solution

salt for sodium cholate to 100 per cent bile salt for the mixture. The maximum cholesterol which could be solubilized by this mixture of conjugated bile salt was 1·7 per cent at 24° C as opposed to 2 per cent for the sodium cholate. While the solubility of the conjugated bile salt mixture is much greater in water than sodium cholate, its capacity to solubilize cholesterol is almost the same.

Quaternary systems. It seemed that the best way to present the quaternary system was to examine the modification of the ternary diagram (bile salt–lecithin–water) when cholesterol was added as a fourth component. Indeed, the addition of cholesterol to the various phases of the ternary system did not change their general structure but simply modified the frontier of their corresponding areas on the diagram. This is clearly shown in the series of diagrams in Fig. 2. Each of these triangular diagrams corresponds to a constant overall percentage of cholesterol—only the percentages of the other three components vary. Thus Fig. 2*a*, which corresponds to 0 per cent cholesterol, is simply a reproduction of the ternary diagram Fig. 1*c* simplified to show only the contours of the four separate phases. The others, Figs. 2*b*–*j*, correspond to overall percentages of cholesterol 0·5 per cent, 1 per cent, 2 per cent . . . 25 per cent.

It can be seen that, in phase I, up to 25 per cent cholesterol can be associated with the lecithin and bile salt. X-ray analysis indicated that in these quaternary systems, phase I remained lamellar, phase II cubic, and phase III hexagonal. The presence of cholesterol in these phases caused a slight increase in the long spacing (D) compared with the corresponding points in the ternary system, just as if the lipid layer was in a more condensed state. This finding is in accordance with what is observed with mixed films of lecithin and cholesterol spread on water[5]. Here the presence of cholesterol reduces the partial molecular area of lecithin, showing that the chains of the lecithin are in a more condensed state.

With these diagrams at our disposal, and given that bile is an aqueous solution containing as its main soluble component bile salt and as its primary insoluble components lecithin and cholesterol, the question naturally arises as to which region of the diagram the gall bladder bile falls in and what might result from variation in its composition.

An average normal human gall bladder bile contains about 92 per cent water, 3·5 per cent bile salt, 3 per cent lecithin, 0·5 per cent cholesterol and 1 per cent other components—for example, bile pigments (mostly in the form of water soluble bilirubin diglucuronide), protein, and inorganic anions and cations. If we neglect the minor changes in Fig. 2 which these other components may produce, we can compare bile with a system having a composition of about 93 per cent water, 3·5 per cent bile salt, 3 per cent lecithin and 0·5 per cent cholesterol, the corresponding point of which falls in the region of the isotropic phase IV at the point marked X in Fig. 2*b*.

The composition of gall bladder bile, especially in pathological cases, has been shown to vary widely[6–8]. If bile is to remain a micellar solution, however, its composition must be within the confines of phase IV. Indeed, from an examination of these diagrams it is possible to predict that a change in the percentage of any of the components (cholesterol, lecithin, bile salt and water) may lead to the formation of crystals of cholesterol or one of the paracrystalline phases (I or III).

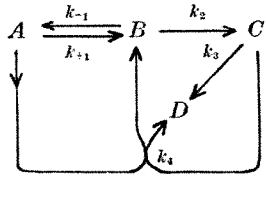
A CHEMICAL REACTION WITH A MEMORY EFFECT

By Dr. W. BRACKMAN

Koninklijke/Shell-Laboratorium, Amsterdam

A MECHANISM frequently encountered in reaction kinetics consists of an equilibrium:



$$A \underset{k_{+1}}{\overset{k_{-1}}{\rightleftarrows}} B, \text{ for which } k_{-1} \gg k_{+1}$$

followed by an irreversible reaction of B:

$$A \underset{k_{+1}}{\overset{k_{-1}}{\rightleftarrows}} B \xrightarrow[k_2]{} C \xrightarrow[k_3]{} D \rightarrow \text{etc.} \qquad \text{(I)}$$

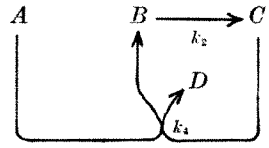
During such a reaction the concentration of B will be smaller than that corresponding to the unperturbed equilibrium $A \rightleftarrows B$, in particular if k_2 is not small relative to k_{-1}.

The present article reports a type of reaction in which the set of equations (I) is contained, but in which during the reaction the concentration of B becomes greater than that corresponding to an unperturbed equilibrium $A \rightleftarrows B$. This unusual behaviour is due to a reaction (4) of A and C, regenerating the intermediate B and yielding the final product D:

(II)

The assumption that $k_{-1} \gg k_{+1}$ is retained throughout this article. Moreover, it is assumed that

reaction (4) is fast* relative to (−1), (2) and (3), and reaction (−1) is not much faster than (2) } conditions α



Then each quantity of B reacting to give C will immediately be replenished by reaction (4). As a result, the concentration of B and thus the reaction rate, $-\mathrm{d}[A]/\mathrm{d}t$, which under these conditions tends to $k_2[B]$, will decrease only slowly, while A may be consumed rapidly. Under these conditions the consumption of A proceeds mainly by way of reaction (4) and only to a small extent by way of (1).

Reactions proceeding by way of mechanism (II) under the conditions α possess some properties which are at first sight paradoxical. For example, the reaction rate is not a single valued function of the concentration of A, because the 'history' of the system also has its effect. This is seen most clearly when the conditions α are fulfilled in the extreme, namely when:

k_{+1}, k_{-1} and k_3 are zero, while $k_4 \rightarrow \infty$ (at least 'very large') and $[B]_0 \neq 0$ } conditions β

* The quantities compared here are the products of rate constants and concentrations.

The condition that B should be given an initial value obviously has to be made in order to start the reaction. Under conditions β the system reduced to:

(III)

In such a system B remains constant and equal to any initially given value $[B]_0$, since any B disappearing by way of (2) is instantaneously regenerated by (4).

Since $[B]$ is constant, the reaction rate $-\mathrm{d}[A]/\mathrm{d}t$ will also be constant, although $[A]$ continuously decreases:

$$\frac{\mathrm{d}[B]}{\mathrm{d}t} = 0 = -k_2\,[B] + k_4\,[A]\,[C]$$

$$-\frac{\mathrm{d}[A]}{\mathrm{d}t} = k_4\,[A]\,[C] = k_2\,[B] = k_2\,[B]_0 = \text{constant}$$

The concentration of C thus increases, being inversely proportional to $[A]$ during the reaction.

(An apparent objection to this reasoning seems to be that, since $\mathrm{d}[B]/\mathrm{d}t + \mathrm{d}[C]/\mathrm{d}t = 0$ irrespective of the values of k_2 and k_4, while $\mathrm{d}[B]/\mathrm{d}t \to 0$ when $k_4 \to \infty$, $[C]$ would have to be constant. In the extreme case β, $[C]$ is indeed constant, namely zero, and the product $k_4\,[A]\,[C]$ can remain constant by virtue of the indefinite value of the product $0 \times \infty$. When k_4 is finite, although $\gg k_2$, $[C]$ will be very small relative to $[B]$. Then $\mathrm{d}[B]/\mathrm{d}t$ will no longer be zero, but have a small value, approximately zero so long as $[A]$ does not tend to zero. The relative changes in $[B]$ will be small, but, since $\mathrm{d}[B]/\mathrm{d}t + \mathrm{d}[C]/\mathrm{d}t = 0$, the relative changes in $[C]$ will be appreciable.)

Now if k_{+1} and k_{-1} are not truly zero, but reactions $+1$ and -1 are negligibly slow relative to the other reactions in mechanism (II), then $[B]_0$ will be a function of $[A]_0$, for example:

$$[B]_0 = K_1\,[A]_0^n \qquad \text{(condition } \gamma\text{)}$$

The initial rates of such a system will then be found to be n^{th} order in $[A]$, if a series of experiments with different initial concentrations of A is carried out. During each experiment, however, the rate will be zero order in $[A]$, since each experiment conserves the initial rate until $[A]$ has dropped to zero. For $n = 1$ this situation is shown in Fig. 1.

It can also be seen from Fig. 1 that the rate $-\mathrm{d}[A]/\mathrm{d}t$ of such systems is not a single-valued function of $[A]$. At a given value of $[A]$, say x, the rate can have any value $\geqslant y$, depending on the "history"—that is the initial concentration of A—of the system.

The phenomena displayed in the most extreme form by mechanism (III) under the conditions β and γ will be referred to as the "memory effect", which has the following characteristics:

(*a*) The rate $-\mathrm{d}[A]/\mathrm{d}t$ is of zero (or very low) order in $[A]$ so long as $[A]$ does not drop to very low values, while the initial rate is of a higher order in $[A]_0$.

(*b*) Consequently, the reaction rate is not a single-valued function of $[A]$—except at the start of the reaction—but is co-determined by the "history" of the system. (The term "memory effect" will be used in connexion with homogeneous systems. In heterogeneous systems the "ageing" of, for example, solid phases provides a simple manner of making the behaviour of the system dependent on its history. A long-known example of a reaction possessing different orders with respect to concentration and to time is the thermolysis of acetaldehyde at 500° (ref. 1).)

If the conditions for a mechanism (II), α, are fulfilled but not in the extreme (like β), then the non-single-valuedness of $-\mathrm{d}[A]/\mathrm{d}t$ as a function of $[A]$ remains, but the rate of separate runs is not exactly constant. An experimental example of this situation is given in Fig. 2. In the course of the reaction the reaction rate decreases far more slowly than the measured concentration.

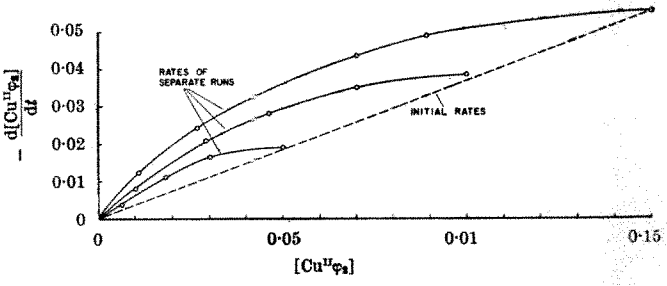


Fig. 2. Plot of reaction rate against concentration in systems $Cu\varphi_2(NO_3)_2$ (0·05 – 0·1 – 0·15 mmole), $NaOCH_3$ (0·2 mmole) and $(t\text{-}C_4H_9)_2NO$ (0·002 mmole) in 30 ml. methanol, 30° C, anaerobic conditions

The differential equations describing the kinetics of mechanism (II) cannot be solved analytically, even for the simplified problem (III), with $k_4 \neq \infty$. The systems (II) and (III) are, however, easily simulated on an electronic analogue computer.

Kinetics of the aforementioned type were encountered in the reduction of cupric–phenanthroline complexes by methanol, catalysed by the stable free radical di-*t*-butyl nitroxide $(t\text{-}C_4H_9)_2NO$.

Solutions of cupric nitrate and *o*-phenenthroline (1 : 2 ratio) in methanol containing some $NaOCH_3$ are stable at 30° C in the absence of oxygen, unless a catalyst is added. In such solutions the copper ion and phenanthroline (φ) largely combine to a complex ion $Cu^{II}\varphi_2$. (The reaction is described in detail elsewhere[2]. In the present article those complications which do not contribute to the "memory effect", such as the further co-ordination of $Cu^{II}\varphi_2$ with φ, CH_3O^- or CH_3OH or the existence of two parallel oxidation reactions of methanol, have been ignored for simplicity.) The latter is comparable with compound A in diagram (II). To a small extent this complex dissociates according to:

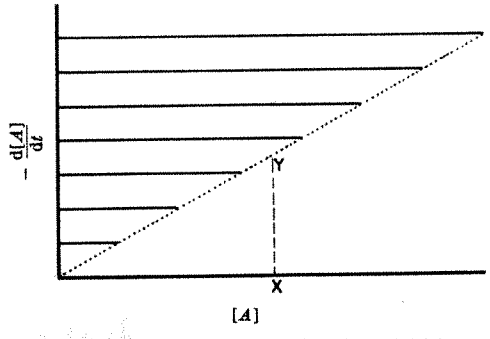
$$Cu^{II}\varphi_2 \rightleftarrows Cu^{II}\varphi + \varphi$$

The kinetics indicate that only the complex $Cu^{II}\varphi$ (B in diagram (II)) is reduced by methanol and a catalyst, to form $Cu^{I}\varphi$ (C). The fate of methanol and catalyst in this reduction is irrelevant to the present discussion. Suffice it to say that their concentrations remain constant throughout the reaction. The co-ordinatively unsaturated cuprous complex $Cu^{I}\varphi$ can be converted into the much more stable $Cu^{I}\varphi_2$ (D) in two ways: (*a*) The reaction with free phenanthroline:

$$Cu^{I}\varphi + \varphi \to Cu^{I}\varphi_2$$

which will be relatively slow because $[\varphi]$ is small. (*b*) An electron transfer reaction with $Cu^{II}\varphi_2$:

$$Cu^{I}\varphi + Cu^{II}\varphi_2 \to Cu^{II}\varphi + Cu^{I}\varphi_2$$



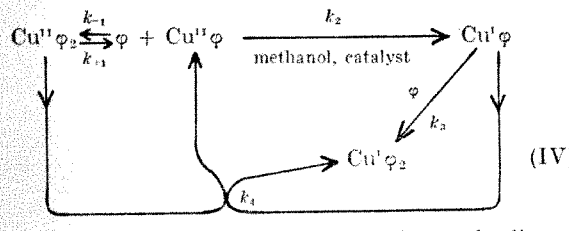


Fig. 1. Full lines, rates of separate runs; dotted line, initial rates. As a function of time the systems run from right to left

(reaction 4 in (II)), which may be expected to be very fast. It provides an efficient way of stabilizing the concentration of the reactive intermediate $Cu^{II}\varphi$.

The individual reactions participating in the catalysed reduction of the cupric phenanthroline complex by methanol can be assembled in a diagram analogous to (II):

(IV)

Experimentally, the reaction is started by adding the catalyst to the methanolic solution of the cupric phenanthroline complex. The total concentration of cupric complexes as a function of time is followed on a recording spectrophotometer. The reaction rates as a function of the concentration are plotted in Fig. 2 for three systems. The initial rates are approximately first order in $[Cu^{II}\varphi_2]$; during the reaction this order is considerably lower. (On the basis of an equilibrium $Cu\varphi_2 \rightleftarrows Cu\varphi + \varphi$, the initial concentration of $Cu\varphi$ and the initial rate would be expected to be proportional to $[Cu\varphi_2]_0^{\frac{1}{2}}$, since $[Cu\varphi]_0 = [\varphi]_0$. The complications giving rise to an approximate first order in $Cu^{II}\varphi_2$ are discussed in ref. 2.) The rate is not a single-valued function of $[Cu^{II}\varphi_2]$, because the system 'remembers' its initial conditions.

The reactions of diagram (IV) were simulated on an electronic analogue computer. k_{-1} and k_3 (which were assumed equal for simplicity) were varied, while k_{+1}/k_{-1}, k_2 and k_4 were given constant values such that the time needed for completion of the reaction was of the order of 5–10 min. It was seen that k_4 needs to be only about $10 \times k_{-1}$ in order to obtain a memory effect comparable to that illustrated in Fig. 2.

I thank Dr. H. A. Vreedenberg for helpful discussions.

SENSE RECEPTORS OF *Multicotyle purvisi* DAWES, 1941 (TREMATODA, ASPIDOBOTHRIA)

By KLAUS ROHDE
Department of Zoology, University of Malaya, Kuala Lumpur, Malaysia

IT is generally assumed that one of the adaptations to a parasitic way of life in Platyhelminthes is a reduction of their sense receptors. It is, therefore, of great interest that in a species of trematode sense receptors were found which are not only more diversified than known from any trematode, but even more complex than in free-living turbellarians.

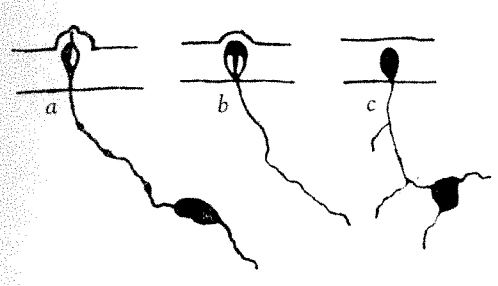

Fig. 1. Three types of sensory bulbs in the oral sucker of *Cercariaeum*. (After ref. 4)

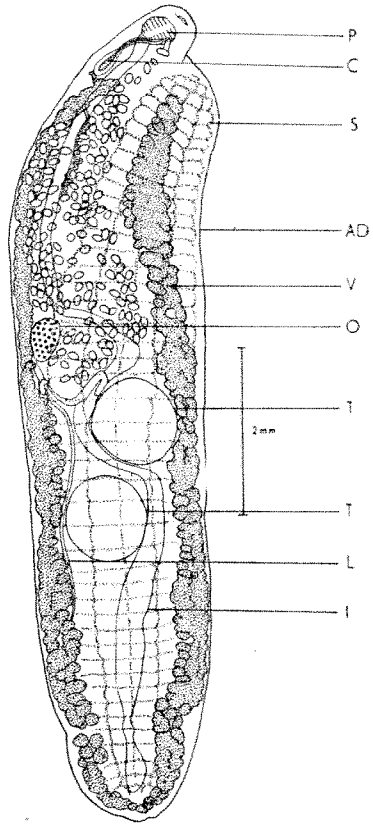
While free-living turbellarians may have, besides eye-spots and statocysts, a variety of sensory bristles, some serving as chemoreceptors, others as tangoreceptors or rheoreceptors (see, for example, ref. 1), the only sense receptors known from digenetic trematodes, are free nerve endings below the cuticle (see especially refs. 2 and 3) and bulb like terminal swellings of neurosensory cells in the cuticle[3–5] (Fig. 1). Eye spots are often present in free larval stages, but are generally lost in the adult parasitic stage. For monogenetic trematodes, Wright and MacCallum[6] describe simple "tactile organs" with a long tactile hair. The marginal organs of Aspidobothria, which were considered to be sense organs by some early authors, are not sensory in nature, but ampulla-like structures filled with glandular secretion.

Zernecke[7], Blochmann[8] and Pintner[9] have shown that cestodes have simple types of sense receptors similar to those of trematodes.

In the course of histological investigations of *Multicotyle purvisi* Dawes, 1941 (Fig. 2), using the slightly modified urea–silver nitrate method as described by



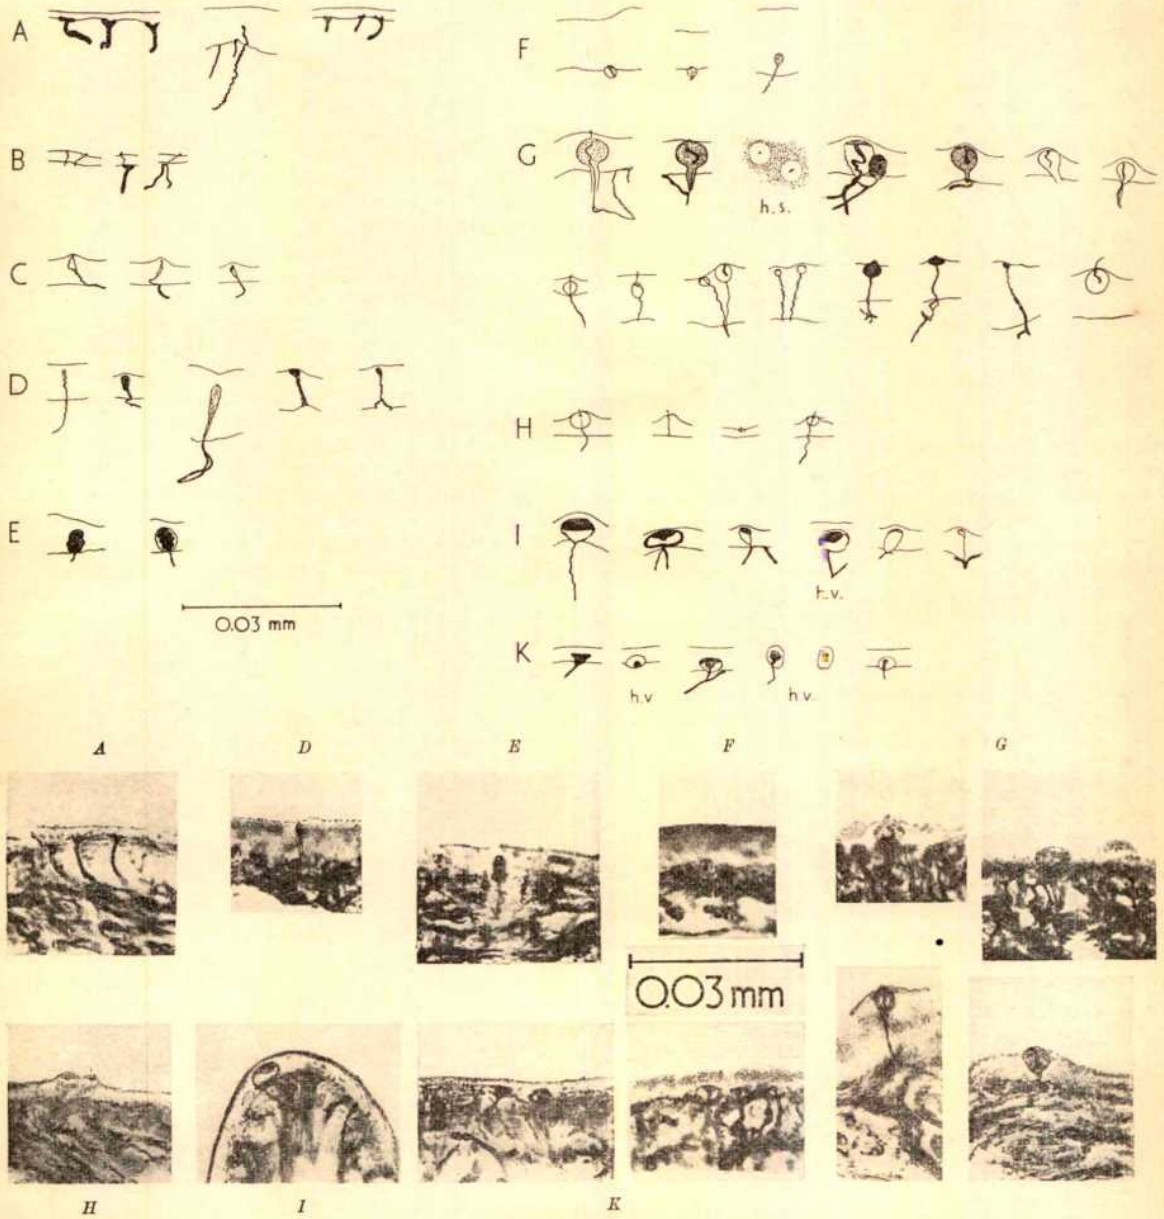


Fig. 2. *Multicotyle purvisi* Dawes, 1941. Whole mount. *P*, pharynx; *C*, cirrus pouch; *S*, suckerlet of adhesive disk; *AD*, adhesive disk; *V*, vitellaria; *O*, ovary; *T*, testis; *L*, Laurer's canal; *I*, intestine

Gurr[10], an astonishing variety of sense receptors was found. This variety is even greater than that of free-living turbellarians. The statement that parasitism in Platyhelminthes leads to a reduction of their sense receptors cannot therefore be applied to this species.

In *Multicotyle*, the least specialized sensory elements are free nerve endings which can be found below the cuticle in most parts of the body (Figs. 3 and 4*A*). They are most common in the suckerlets of the adhesive disk and on the walls separating them, and in the oral opening and the region surrounding it and behind it. They occasionally penetrate a short distance into the cuticle. Often their ending is branched in a T-like fashion. They must not be confused with the network of connective tissue the fibres of which often look very similar, especially those in the suckerlets of the adhesive disk. Because of this similarity, the connexion of a fibre to large nerves was used as the only criterion for its nervous nature. Free sense hairs are very common on the adhesive disk and probably in the oral opening; they arise from the subcuticular nerve endings and pierce the cuticle to form a small knob-like projection on its surface (Fig. 3*B*). On rare occasions, such sensory hairs were also seen penetrating the thick dorsal cuticle. It is, however, possible that these are in fact secretory ducts. (In the suckerlets, the hairs could often be traced to the free nerve endings which supports the view that they are of a sensory nature. However, it cannot be ruled out that at least some of the "hairs" are secretory ducts and the knob-like projections secretory droplets. Final clarification of this point would be possible by investigations with an electron microscope.)

Relatively few nerve fibres penetrate into the cuticle-forming loops (Fig. 3*C*) or clubs consisting of a coiled up nerve fibre (or fibres ?, Figs. 3 and 4*D*). While the former were mainly found on the adhesive disk, the latter are thinly scattered on the lateral and dorsal parts of the main body. Sometimes, the clubs are solidly stained, thus concealing any fibres.

Figs. 3 and 4. Sense receptors of *Multicotyle purvisi* Dawes (Fig. 3, camera lucida drawing; Fig. 4, photographs). *A*, Free subcuticular nerve endings; *B*, free sensory hairs; *C*, loops of nerve fibres in cuticle; *D*, coiled up nerve fibres and small clubs in cuticle; *E*, large clubs in cuticle around mouth opening; *F*, small subcuticular capsules; *G*, capsules in cuticle; *H*, small capsules in cuticle of adhesive disk; *I*, sensory bodies in cuticle of walls separating suckerlets of adhesive disk; *K*, small sensory bodies in and around mouth; *h.s.*, horizontal section; *h.v.*, horizontal view

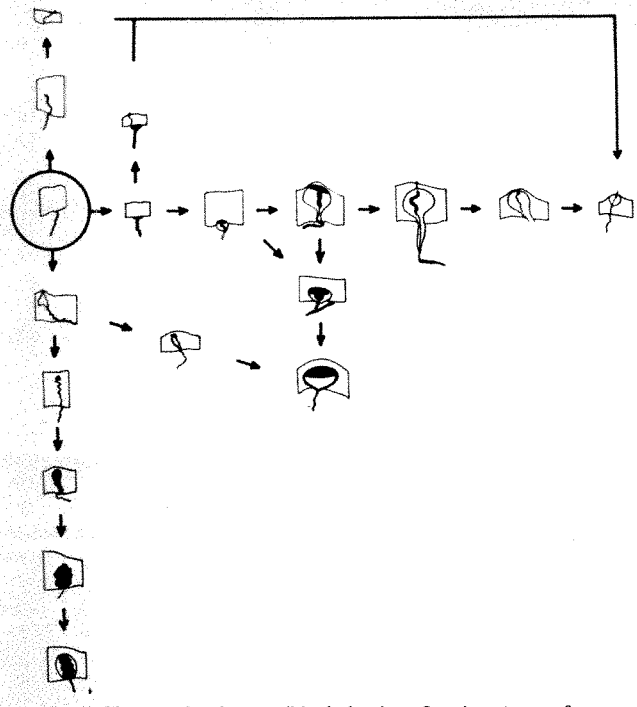

Fig. 5. Diagram showing possible derivation of various types of sense receptors

Common in the region around and behind the oral opening (but absent in the mouth cavity) are large, solidly stained bodies which are sometimes surrounded by a capsule (Figs. 3 and 4*E*, maximum size 6·0 × 3·6μ). It is possible that these are derived from the smaller clubs in other parts of the body.

Small capsules are dispersed throughout the region below the cuticle of the main body. They can be considered to be free T-shaped nerve endings surrounded by a capsule (Figs. 3 and 4*F*, maximum size 5·4 × 3·6μ, usually about 2·5 × 2·5μ). The terminal solid plate is often absent. Occasionally, the capsules penetrate for a short distance into the cuticle. An apparent further development of these small subcuticular capsules are large capsules which are distributed in most parts of the body. They are often located in an elevation of the cuticle and show a considerable variability in size (Figs. 3 and 4*G*, maximum size 7·0 × 7·4μ). They are largest and most common in the regions dorsal and lateral to the oral opening (but not in the mouth cavity) and rarely occur on the adhesive disk. Typically, the capsule is a pear-shaped body with a long projection reaching below the cuticle. A thick nerve fibre crosses the capsule, forming an S-shaped figure in its widest part. Terminally, it either forms a solid plate which sometimes bears a short hair-like process passing beyond the surface of the cuticle, or it occurs without such a plate, and becomes very thin and often passes to the surface where it forms a knob-like projection or a long sensory hair. In horizontal sections, the capsule appears homogeneous and surrounded by a strongly granular cuticle. A modification of this kind of capsule is the smaller capsule found on the ventral disk, in the lumen of the mouth cavity, on the lip surrounding the mouth opening, and in the regions ventral and lateral to the mouth opening (Figs. 3 and 4*H*, maximum size 3·4 × 3·6μ). In this type, there is no thick S-shaped fibre in the capsule. Instead, the fibre is usually straight and extremely thin and forms a very long sensory hair at the surface. Normally, there is a small plate-like swelling of the fibre at the base of the hair which probably corresponds to the body of discrete amorphous material described by Dixon and Mercer[5] in the sensory bulb of the cercaria of *Fasciola hepatica*.

Large bodies are very conspicuous and common on the walls separating the suckerlets of the adhesive disk (Figs. 3 and 4*I*, maximum size 6·0 × 7·2μ). The large terminal plate of this sense receptor seems to consist of a fused nerve fibre. Sometimes the end plate is very thin, which indicates a possible relationship with the simple nervous loop (see Fig. 3*C*). It is also possible that they are derived from the large pear-shaped capsules (see Figs. 3 and 4*G*) in which the terminal plate has become abnormally thick. This is indicated by the structure of smaller capsules which are very common on the lip around the oral opening and inside the mouth cavity (Figs. 3 and 4*K*, maximum size 3·0 × 4·1μ). These capsules resemble the receptors illustrated in Figs. 3 and 4*G*, but they have an extremely thick terminal nerve fibre and usually a very thick terminal plate. The possible relationship of the various types of sense receptors is illustrated in Fig. 5.

The number of sense receptors is greatest around and behind the mouth and on the adhesive disk. In a specimen, 6·1 mm long, the following numbers of receptors were counted: in the prepharyngeal region (310μ long), dorsal, 360; ventral, 260; in the mouth cavity, 140. Most common in the mouth cavity and on the lip surrounding it were sense receptors, as illustrated in *K*, but there were also many '*H*'s'. In the regions dorsal, lateral and ventral to the oral opening there were mainly '*G*'s', but also a considerable number of '*E*'s'. Besides the sense receptors, numerous free nerve endings were present.

In another specimen, 3·1 mm long, the posterior half of the prepharyngeal region (100μ long), excluding the mouth cavity, contained about 160 sense receptors, while a portion of the body, 300μ long and beginning 600μ behind the anterior end, contained about thirty-five '*I*'s', sixty '*H*'s', thirty-five '*C*'s' and a great number of sensory hairs and free nerve endings on the adhesive disk, and seventy '*F*'s' and '*G*'s' and five '*D*'s' on the main body, primarily its dorsal portion. A part of the body, 300μ long and beginning 2·9 mm behind the anterior end, contained about forty '*I*'s', 115 '*H*'s', ten '*C*'s' and a great number of sensory hairs and free nerve endings on the adhesive disk, and twenty-five '*F*'s' and '*G*'s', five '*H*'s' and two '*D*'s' on the main body. There were hundreds of free nerve endings and at least some dozen free sensory hairs in each suckerlet of the adhesive disk.

The numbers given are only approximate and probably minimum values, because it is often difficult to count all sense receptors, especially in areas where they are closely packed. Most difficult to find are the small bulbs located below the cuticle ('*F*').

After staining in hot 2 per cent silver nitrate solution, the openings of the sensory bulbs appear as black spots on the cuticle. It is doubtful, however, whether all bulbs are stained, especially those without a hair piercing the cuticle. Thus, this method cannot be used for counting the sense receptors.

Regarding the function of the different receptors, it seems probable that '*A*', '*F*', '*I*' and '*K*' are tango-receptors, because they do not possess hairs which might be stimulated by chemicals. No statement about the function of the other types is possible at present.

I thank Miss Lilian Lim and Mr. Teh Kok Leng for their technical assistance. This work was supported by a grant from the Deutsche Forschungsgemeinschaft.

MORPHOLOGICAL AND SEROLOGICAL ANALYSIS OF LEPTOSPIRAL STRUCTURE

By PROF. R. YANAGAWA and PROF. S. FAINE
Department of Bacteriology, University of Sydney, Australia, and Department of Veterinary Microbiology, Faculty of Veterinary Medicine, Hokkaido University, Sapporo, Japan

THERE is no serological or chemical information about the nature of the morphologically identifiable structures of the leptospiral cell nor have there been investigations of the cellular localization of antigenic sites. This information is of importance in microbiology because of the unique structure of the genus *Leptospira* and its relationship to the structure of other genera of spirochaetes, and of taxonomic importance because of the complex and increasingly confusing serological relationship between serotypes of leptospires. An understanding of leptospiral structure may help elucidate some unexplained aspects of the pathogenesis of leptospirosis[1]. This article reports the morphological identification and partial purification of cell-walls from pathogenic *L. icterohaemorrhagiae*, describes perimural fibrils and suggests the nature of antigens corresponding to various cellular components.

It has been generally agreed that leptospires have three main structures, a protoplasmic cylinder, an axial filament and a cell envelope[2]. As a result of thin sectioning of leptospires Babudieri[3] showed that the axial filament was covered by and located inside the envelope. Simpson and White[4] reported that the protoplasmic spiral was a hollow tube which contained material of low electron density.

Serologically-active antigenic fractions of leptospires have been extracted with ethanol[5–8], deoxycholate[9] and phenol[10], but no morphological observations were made of the cellular location of extracted material. Recently, Ginger[11] identified muramic acid in *Borrelia duttoni* and *L. biflexa*. He suggested that spirochaetes should have cell-walls structurally similar to the bacteria.

In the present experiments *L. icterohaemorrhagiae* was cultivated in Korthof's medium with 8 per cent rabbit serum for 4–7 days at 30° C, washed twice with 0·01 M phosphate buffer, *p*H 7·2, and resuspended in buffer to one-twentieth of the volume of the original culture.

Initially, serologically antigenic fractions were extracted from the washed cell suspensions by the following agents: ethanol (final 50 per cent, 4° C overnight, repeated more than twice), *n*-butanol (final 50 per cent, shaken at room temperature for 5 min, 4° C overnight, aqueous phase used), ethyl ether (excess amount, shaken for 5 min and kept overnight at room temperature, aqueous phase used), phenol (final 50 per cent, 65° C for 10 min, aqueous phase used), sodium deoxycholate (L. Light and Co., final 1 per cent in 0·01 M phosphate buffer solution, *p*H 7·2, 45° C for 4 h), trypsin (B.D.H., 1 mg/ml. in 0·06 M phosphate buffer solution, *p*H 7·8, 37° C up to 3 h), lysozyme (Armour, 20–1,000 μg/ml.), penicillin (10–100,000 U), DNase (Sigma, 0·5 mg/ml.), RNase (N.B.C., 0·5 mg/ml.). A Hughes bacterial press[12] was also used. Ethyl ether, *n*-butanol and ethanol were removed from the aqueous phase by evaporation at 37° C. The extracts or soluble parts were separated from the cell residue by centrifugation and used as antigens for precipitin reaction in gels. Cell residues, examined by light and electron microscopy, were also used as antigens in agglutination. Precipitin reaction in gels and agglutination-lysis tests followed standard techniques. Homologous strain antiserum was obtained by immunizing rabbits with whole cultures of intact leptospires, yielding an agglutination-lysis titre of 10^{-4}.

For electron microscopy, residual cells after washing and further treatment were fixed overnight at 4° C in 0·5 per cent osmium tetroxide in veronal buffer, *p*H 7·3. Fixed leptospires sedimented by centrifugation at 17,000–25,000*g* for 30 min and washed twice with distilled water were mounted on Formvar' grids, and either shadowed with gold–palladium at an angle of 30° or stained with 2 per cent phosphotungstic acid which was adjusted with 1 N potassium hydroxide to *p*H 7·2 or were hardened in 2 per cent agar, dehydrated, embedded in 'Araldite' and sectioned with an '*LKB* 4800*A*' ultratome. Sections were stained with either phosphotungstic acid or lead[13] and examined in a Siemens 'Elmiskop I' electron microscope at initial magnifications up to 40,000 times.

Estimations of muramic acid and glucosamine were made spectrophotometrically following the method of Park, described by Perkins and Rogers[14].

Washed leptospires were treated as described and the antigenicity of the supernatant fractions was examined by precipitin reactions in gels with immune serum against whole organisms. Ethanol and *n*-butanol extracts each contained an antigenic fraction which gave three similar lines. Phenol extracted a similar antigenic fraction which gave a faint line. No appreciable antigenicity was found in the extract or supernatant of the cells treated with ether, trypsin, lysozyme, or penicillin and in the cells disrupted with the Hughes press.

Treatment with deoxycholate produced a fraction containing antigens which formed five lines, including all three of those found in ethanol, *n*-butanol and phenol extracts. The common lines were spaced near the anti-serum well or between the anti-serum and antigen wells, while the characteristic lines of deoxycholate extracts were formed close to the antigen well (Fig. 1). Residues of the cells treated with ethanol or *n*-butanol could be further extracted with deoxycholate. The extract thus produced gave three or four lines, which included all the lines characteristic of deoxycholate and also one or two lines common to ethanol or *n*-butanol extracts.

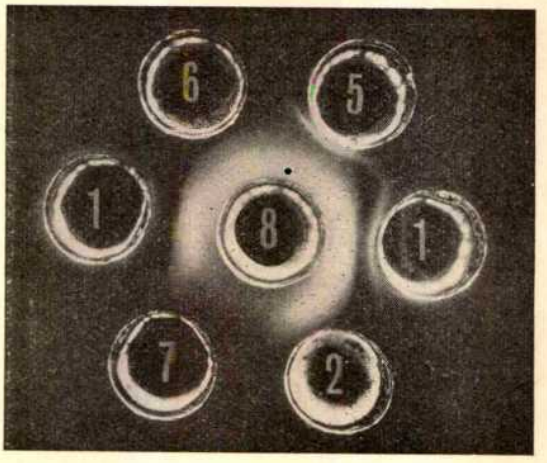

Fig. 1. Immunodiffusion of rabbit antiserum to whole *L. icterohaemorrhagiae* (8) with the following extracts of homologous leptospires: deoxycholate (1), butanol (2), deoxycholate extract of ethanol-treated cells (5), ethanol (6) and phenol (7)

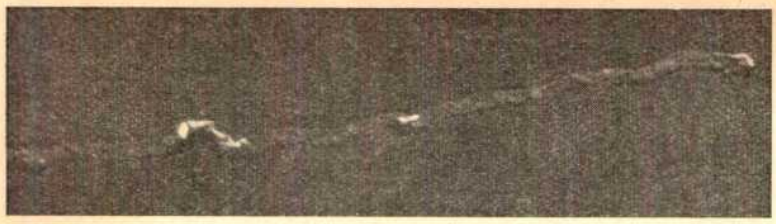

Fig. 2. Cell wall of *L. icterohaemorrhagiae*. A vestige of spiral structure remains where there is adherent perimural material. Shadowed electron micrograph. (× *c.* 11,850)

The optical density of leptospiral suspensions was reduced within 0·5–1 h when treated with deoxycholate and was further reduced after washing and trypsinization. Suspension density was also reduced after pressing but not by other treatments. Under dark-field, leptospires were seen to retain their shapes. Trypsin caused a slight reduction and deoxycholate a great reduction in refractility which was not appreciably changed by ethanol, *n*-butanol, ether or phenol. When the cells were treated with trypsin after deoxycholate, the refractility was greatly decreased. Pressing caused leptospires to agglutinate into large clumps allowing the individual apparently disrupted cells to be seen only with great difficulty.

Under the electron microscope, whole leptospires clearly showed their three basic structures—namely, a protoplasmic cylinder, an axial filament and a cell envelope. A regular fold or apparently cord-like structure twisting all over the protoplasmic body was noticed under the envelope.

Ethanol treatment caused incomplete removal of the envelope and the axial filament but the electron density was not reduced. After deoxycholate treatment with constant shaking, the outermost cell envelopes were removed and the axial filaments were completely lost. Cells thus treated appeared to have surfaces rougher than when untreated, and their electron density was lowered.

Trypsinization of cells already treated with deoxycholate made the leptospires flat, straight and less electron-dense. Occasionally a fibrous structure was revealed on the cell body, details of which are described in a later paragraph. Similar results were also obtained when trypsinization was applied to the cells treated with both ethanol and deoxycholate. Almost all nucleic acid, measured by the absorption of 260 mμ of a 1 N perchloric acid extract (70° C for 20 min), was lost from the deoxycholate and trypsin-treated cells. Agglutinability was reduced by these treatments (Table 1).

Table 1. AGGLUTINABILITY OF LEPTOSPIRES AFTER CHEMICAL TREATMENT

Leptospiral antigen suspension after treatment with	Morphology	Reciprocal agglutination-lysis titre (50 per cent agglutination end-point)
—	Whole cells	10,000
50 per cent ethanol, nine times	Cells only partially deprived of envelopes and axial filaments	1,000
Deoxycholate and DNase	Cells deprived of envelopes, axial filaments and DNA	100
Deoxycholate, trypsin, DNase and RNase	Only cell walls and some protoplasmic material	100

Table 2. MURAMIC ACID AND GLUCOSAMINE IN LEPTOSPIRES AFTER CHEMICAL TREATMENT

Leptospires treated with	Morphology	Muramic acid (per cent dry wt.)	Glucosamine (per cent dry wt.)
—	Whole cell	0·7	2·4
Deoxycholate and DNase	Cells deprived of envelopes, axial filaments and DNA	2·6	3·3
Deoxycholate, trypsin, DNase and RNase	Cell walls with some cytoplasmic materials	3·7	4·0

After shaking successively with deoxycholate, trypsin, DNase, and RNase, the preparations under the electron microscope showed filamentous cell residues with some intracytoplasmic material still remaining. Estimation of muramic acid and glucosamine (Table 2) showed that the proportionate muramic acid content of leptospires was gradually increased during progressive purification. This is evidence that the flat filamentous shape contains muramic acid and that it could be cell wall. Glucosamine content was similarly increased progressively during purification but the increase was less than in the content of muramic acid (Table 2). These findings confirm the conclusion that the long filamentous shape was the leptospiral cell wall and thus the basic morphological entity of leptospires. Cell walls were further purified by more drastic procedures including pressing which did not clump cell walls as it did whole cells. The preparation obtained after treatment with deoxycholate, DNase, trypsin, pressing, deoxycholate, DNase, trypsin and RNase is shown in Fig. 2. Many of the cell walls were straight, very flat and contained apparently internal granules. Occasionally foldings were seen which may have been an indication of their original spiral. The width of the purified cell walls was about half that of the whole cells. Thin sections of leptospires were examined to observe particularly their cell walls. A section of a whole leptospira (Fig. 3) showed the three main structures and also demonstrated a three-layered cell wall consisting of a less dense layer between two denser layers. Partially purified cell walls showed a lightly staining tubular appearance when sectioned, but bounding membranes were not clear.

In the course of electron microscopy, fine fibrils were observed in preparations which had been treated with deoxycholate without shaking and immediately fixed with osmium tetroxide. Ten min trypsinization after deoxycholate treatment also clearly showed several fibrils twisted around cell walls (Fig. 4) but longer trypsinization of 0·5–1 h destroyed them. They were never seen in whole cell preparations not treated with deoxycholate. Some fibrils remained attached to the cell body by one or both ends, while others were released at one or both ends. On each leptospira there appeared to be six or more fibrils each estimated to be 60–80 Å in individual diameter, and wound or tightly coiled around the leptospiral cell wall as seen in shadowed preparations. The fibrils were clearly different from the axial filament because they were coiled or wavy, were never seen in untreated cells, and were observed either in cells where an intact axial filament could be seen attached to one end, or after treatments where the axial filament was completely released. The most suitable treatments to demonstrate the fibrils were different from those required to show cell walls. The protein composition of the fibrils was suggested by their susceptibility to prolonged trypsin treatment and their staining with phosphotungstic acid. Loss of the spiral shape coincided with the loss of fibrils

Fig. 3. Thin section of a leptospira, (Karkovsky lead strain) (× 40,000). A triple-layered structure corresponding to cell wall is seen between the two darkly-stained masses of axial filament

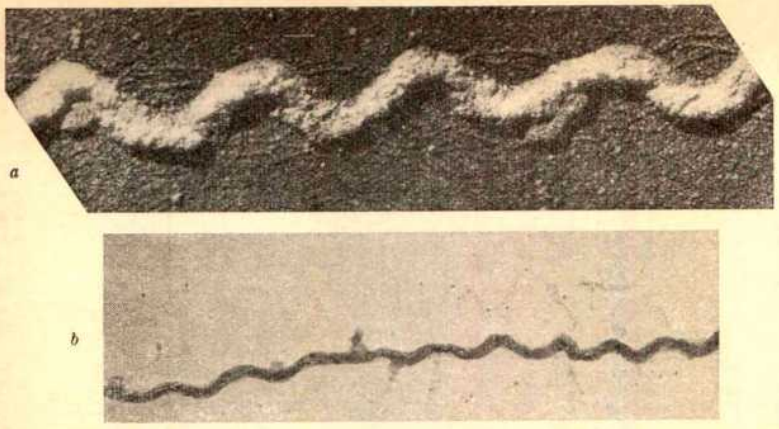

Fig. 4. (*a*) Spiral fibrils between leptospiral spirals seen after treatment of a leptospira with deoxycholate and trypsin. The axial filament of this leptospira was attached at one end, but apparently intact (× *c.* 27,000). (*b*) Fibrils positively-stained with phosphotungstic acid in a parallel preparation to that shown in *a* (× *c.* 13,500)

or their matrix after trypsinization. This body of evidence points to the fibrils as a structural entity distinct from cell wall and axial filament, possibly responsible for the spiral shape by coiling like a tight spring around the cell wall to produce a spiral structure.

The findings show that leptospires are bacteria with cell walls structurally and chemically similar to other bacteria. However, methods such as crushing or decompressive rupture[15] appear to be unsuitable for preparing cell walls without chemical treatment beforehand. Sodium deoxycholate does not cause complete lysis, as is commonly supposed, but strips the outer cellular layers, causing reduction of optical density and of refractility in dark-field, and immediate leakage of intracellular enzymes[16].

Three main layers may now be recognized in the leptospira. The outermost envelope is removed both by 50 per cent ethanol and deoxycholate, which also loosens and removes the deeper perimural fibrillar layer. Although the ethanol extract contains the erythrocyte sensitizing (HL) carbohydrate[5,17] it also removes protein antigens on repeated extraction[8], probably from layers deeper than the envelope. Since agglutinability is reduced after repeated alcohol extraction and almost completely absent in cell wall preparations (Table 1) and anti-HL antiserum does not agglutinate (unpublished observations), the agglutinating antigens are deeper than the envelope and in the perimural layer. The second layer comprised the perimural fibrils and their matrix. It is possible that the perimural fibrils correspond with those thought by Mölbert[18] to originate in the axial filament, by Simpson and White[4] to be in the thick wall of the protoplasmic cylinder, and seen in "degenerating" leptospires[19].

The fibrillar perimural structure may be of taxonomic importance among members of the Treponemataceae. Fibrils, usually thought to originate from the axial filament or bundle, may be found in *Borrelia* or *Treponema*[20]. Further experiments are clearly required to elucidate whether they may not correspond to the perimural fibrils of *Leptospira*. It would also be important to establish to what extent differences in the nutritional environment are reflected in metabolic changes manifested as qualitative or quantitative changes in antigenic constitution and in structure. The third layer beneath the fibril-containing perimural layer is the triple-layered cell wall proper, containing muramic acid and enclosing the cytoplasmic contents. It is not spiral but is a straight, hollow, collapsible tube. Given that the axial filament is flexible as well as straight, these observations are compatible with and explain the infinite flexibility of spirochaetes in semi-solid environments and their immediate return to a straight form in liquids.

The last main structural component is the axial filament which Ritchie and Ellinghausen[19] showed to be multi-stranded within a sheath and suggested was double. Neither duplicate nor multiple axial filaments were seen. However, although the evidence for more than one axial filament is inadequate, it is very likely on theoretical grounds that two axial filaments may be found. The axial filament may be regarded as a locomotor organelle attached to an end-knob inserted into or originating from an intracellular specialized apparatus[19] from which originates a presumably electrical contractile impulse. In a fluid the movement of the axial filament causes the spiral to rotate and the leptospira to move. The possible arrangements are (1) a single axial filament inserted at one end, (2) a single axial filament inserted at both ends, (3) a double axial filament inserted at one end, and (4) two axial filaments inserted one at each end.

In order to explain the movement in both directions in cases 1 and 3 it is necessary to assume that an end-knob apparatus can generate such an impulse either away from it or towards it. It is hard to envisage a mechanism to explain a centripetal impulse, so that it is unlikely that there can be only one end-knob. Furthermore, in cases 1 and 3 the possibilities on division are that (*a*) dissimilar daughter cells will be formed in one of which the axial filament is unattached and thus non-functional, (*b*) the daughter cell which did not receive a maternal end-knob will form one and unite it with the existing fragment of inherited axial filament; this idea envisages a unique and highly improbable mechanism for the newly-formed intracellular end-knob to "trap" and unite to form a functional physiological unit with an existing axial filament which lies outside a considerable layer of cell wall and perimural material. Alternatively a new end-knob may be formed, leading to the growth of a new axial filament or filaments in addition to the unattached fragment derived from the mother cell. In case 2, the axial filament may divide with cell division but in subsequent generations the problems must be the same as described for (1) and (3), unless the alternative is envisaged that there is formation of a new end-knob and "trapping" of the axial filament as in (*b*). If a new end-knob and axial filament were grown, the daughter cells would have two axial filaments as in (4). In case 4, two axial filaments are each attached to a terminal end-knob. On division, there would be two similar daughter cells, each capable of prompt formation of a new end-knob at the newly-formed end, able to give rise to an axial filament which would elongate as the leptospira lengthened, until the form of the parent cell was attained. Thus the criteria of morphological similarity of daughter cells with mother cells and with each other, of simplicity and of microbiological and biological probability are fulfilled. It would be possible to test this hypothesis of axial filament formation by investigating the distribution of forms corresponding to all stages in (4) in cultures during conventional or during synchronized growth. A similar mechanism of replication of multiple axial filaments in *Treponema* species has been published by Listgarten and Socransky[21].

This work was supported by a grant from the National Health and Medical Research Council, Canberra. One of us (R. Y.) carried out this work under a Phyllis M. Anderson Research Fellowship at the University of Sydney in 1964 while on leave from Hokkaido University. We thank Dr. K. W. Knox and Mrs. E. Hall for chemical estimations, Prof. D. A. Cameron, Mr. E. J. Smythe and Miss S. Pemberton for electron microscopy, and the

Department of Medical Illustrations, University of Sydney, for the photographs.

ONCOGENICITY OF BRYAN STRAIN ROUS SARCOMA VIRUS FOR RODENTS

By PROF. R. BATHER, A. M. FERGUSON and A. LEONARD

Saskatchewan Research Unit of the National Cancer Institute, University of Saskatchewan, Saskatoon, Canada

ALTHOUGH certain strains of Rous sarcoma virus (RSV) were known to induce tumours in rodents[1–3], it was not until very recently that the Bryan strain of RSV showed evidence of similar properties. Rabotti *et al.*[4] described gliomata induced in hamsters inoculated intracerebrally with high doses of Bryan RSV and it was suggested by these authors that the virus may contain a mixture of two types of RSV, one affecting only birds and the other affecting both birds and mammals. The latter, if present in small amounts, would only become apparent if high doses of Bryan RSV were used to inoculate mammals. Eidinoff *et al.*[5] obtained subcutaneous sarcomata in hamsters injected with high doses of Bryan RSV, but so far no reports have appeared of tumour induction in mice and rats with this virus.

The RSV used in this laboratory was originally obtained from Dr. W. R. Bryan (National Institutes of Health, Bethesda) in 1959 as a frozen sample of "high titre" virus. This was inoculated into young (4-week-old) East Lansing line 15 White Leghorn chicks obtained through the courtesy of Dr. C. le Q. Darcel from a flock reared in isolation by the Canada Department of Agriculture, Animal Diseases Research Institute (Western), Lethbridge, Alberta. The resulting tumour tissue was used as a source of virus for further inoculation and ever since then either crude cell-free tumour homogenate or tumour cells themselves have been passaged weekly in the same line of chicks in order to maintain a constant supply of virus or cells. Throughout this time many assays of the RSV content of the tumours have been made. These have been performed either on the chorioallantoic membranes of fertile eggs or in tissue culture by the method of Temin and Rubin[6]. Eggs and embryos from a flock of White Leghorns maintained in isolation by the Poultry Science Department of this University were chosen for this purpose after considerable testing of available sources. Over the years the assays have consistently shown that the tumours yield 10^6–10^8 or more pock or focus forming units of virus per gram.

During the past 6 years we have frequently attempted to induce tumours in rodents with our RSV without success. The first indication that this virus was oncogenic for mice came to our attention as a result of an experiment designed to test the possible effects of inositol protection[7,8] of RSV on its infectivity for other species and the "activation" of RSV by a factor in fast-growing tissues as described by Stewart and Landon[9].

Crude RSV was prepared by homogenizing tumour tissue either in Hanks's balanced salt solution (BSS)[10] or 5 per cent myo-inositol solution. Mouse embryo extract (MEE) was prepared by homogenizing near-term Swiss embryos in an equal volume of BSS or 5 per cent inositol and centrifuging to clear the homogenate of cells and debris. Portions of MEE were mixed with part of the corresponding virus suspensions and BSS or 5 per cent inositol were added to other samples of the virus suspensions so that each animal received the same amount of virus. The original virus preparations were assayed in fertile eggs and the virus mixtures were inoculated subcutaneously into newborn (24 h old) Swiss mice. These mice were originally obtained from Connaught Medical Research Laboratories, Toronto, and have been pen-bred and maintained for several years at this University.

Table 1. INCIDENCE AND TIME OF APPEARANCE OF TUMOURS AFTER THE INOCULATION OF RSV IN VARIOUS MEDIA INTO NEWBORN SWISS MICE

Litter inoculated with 10^5 P.F.U.* RSV in the following media	No. of mice	No. of tumours	Time of appearance of tumours (weeks)	Tumour incidence (%)
BSS	21	14	9–30	66
5 per cent inositol	16	10	10–28	63
BSS + MEE	13	5	10–30	38
5 per cent inositol + MEE	18	7	9–22	39

* Pock forming units (chorioallantoic membrane assay).

It is apparent from Table 1 that tumours appeared in all groups of mice within 9–10 weeks after inoculation. No evidence was found of any enhancing effect of either inositol or MEE on the ability of RSV to infect Swiss mice.

Several of the tumours arising were transplanted to both newborn and adult Swiss mice and one is at present in its fifth passage. The latent period of appearance of this tumour is now approximately 2 weeks in adults given 0·2 ml. of a 1 : 10 tumour cell suspension subcutaneously. Attempts to transplant several of the tumours to 4-week-old chicks have failed, which indicates that no infective RSV is elaborated by the cells. Histological sections were made of many of the neoplasms and stained with haematoxylin and eosin. Most of them could be characterized as anaplastic spindle cell sarcomata and, in some cases, fibrosarcomata (Fig. 1). Rhabdomyoblast-like cells were observed when invasion of skeletal muscle occurred, as described for hamster RSV-induced tumours by Eidinoff[5] (Fig. 2). The results of this experiment were surprising in view of our failure to show any ability of Bryan strain RSV to infect mice in previous tests with similarly potent virus extracts. It was of interest, therefore, to see if the virus could induce tumours in rats as well.

Two litters of newborn Wistar rats were inoculated with approximately 10^5 pock forming units RSV subcutaneously. Within 10 days, fluid-filled cysts developed in some of the animals. At 3 weeks after inoculation, one animal was killed and on autopsy was found to have two cysts each approximately 1·0 cm in diameter and a solid tumour weighing 1·3 g. Within 3 months all but one of the

seventeen rats injected had developed multiple cysts and tumours (often weighing several grams), usually with both types of lesions appearing in the same animal. It was frequently observed that small tumours grew from the interior walls of the cysts and this was confirmed by histology. The tumours were all anaplastic spindle cell sarcomata which tended to remain encapsulated until well advanced (Fig. 3). No evidence of metastasis was found in mice or rats even in animals dying with tumours they had carried for several months. Attempts to transplant the rat tumour cells to both rats and chickens failed, the latter observation indicating that no RSV was produced by the cells as was the case with the mouse tumours.

We have never used Schmidt-Ruppin RSV in our laboratory. However, in view of the close similarity of the behaviour of our RSV with the Schmidt-Ruppin strain it was felt of importance to try to establish by neutralization tests whether our RSV had altered its antigenic properties. Through the courtesy of Dr. Robert M. Dougherty, of the Department of Microbiology, Upstate Medical Center, Syracuse, New York, we obtained samples of chicken antisera to both Bryan strain and Schmidt-Ruppin RSV. Neutralization tests were performed by mixing known amounts of our RSV with known amounts of the antisera and incubating for 1 h at room temperature before assaying on chick embryo cells. The results of two tests are given in Table 2.

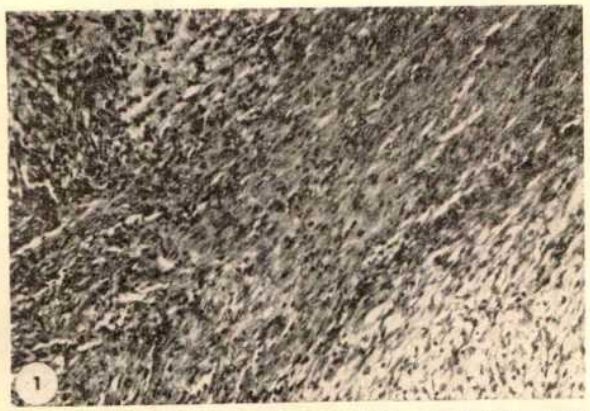

Table 2. EFFECT OF INCUBATING OUR RSV WITH CHICKEN ANTISERA TO BRYAN STRAIN AND SCHMIDT-RUPPIN RSV FOR 1 H AT ROOM TEMPERATURE BEFORE ASSAY IN TISSUE CULTURE

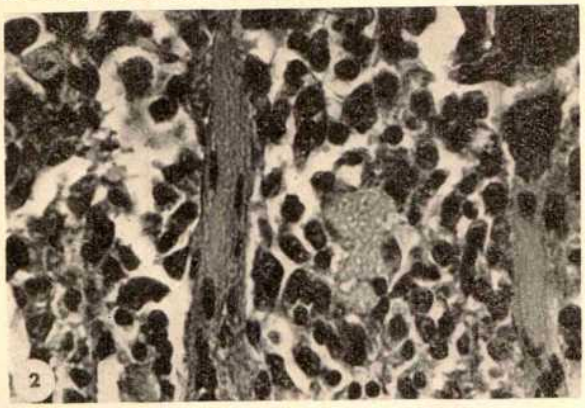

Type of antiserum	Focus-forming units per plate Exp. 1	Exp. 2
None	170	300
Anti-Bryan (> 250 units)	0	0
Anti-Schmidt-Ruppin (> 50 units)	11	65

Although only small amounts of Schmidt-Ruppin antiserum were available for the tests, it is apparent that our RSV was neutralized by both types of antiserum. It should be pointed out that no cross-neutralization occurs when these antisera are reacted with the heterologous virus. Comparison of the morphology of the foci formed in tissue culture by our virus with those formed by Bryan and Schmidt-Ruppin viruses showed that our virus converted chick fibroblasts to typical Bryan foci consisting mainly of round cells and quite unlike those produced by Schmidt-Ruppin virus. This was confirmed for us by Dr. Dougherty[11].

Three properties of our RSV confirm that we still maintain in this laboratory a virus which has retained the characteristics of Bryan strain RSV. These are: (1) consistent and high virus titres found in tumours resulting from its inoculation into young chicks (10^6–10^8 pock-forming or focus-forming units per gram of tissue); (2) complete neutralization by Bryan chicken antiserum; and (3) the round-cell morphology of foci produced in tissue culture. The last property is shared by some other strains of RSV, but not by Schmidt-Ruppin virus. That a change has occurred in the virus is borne out by its neutralization by Schmidt-Ruppin antiserum and by its ability to produce tumours in mice and rats. Further evidence for such a change is provided by the observation that the virus will produce tumours in newborn hamsters with the very short latent period of 2 weeks. Whether or not the antigenic change noted here has anything to do with the oncogenicity of our RSV for rodents is open to question, especially in view of the recent report of Eidinoff *et al.*[5]. These authors used RSV obtained directly from Dr. Bryan for their demonstration of tumour induction in hamsters.

It is true, however, that there now seems to be no difference between the European and North American strains of RSV in their oncogenicity for rodents except for their relative virulence. Further work with our strain is under way including immunological and cytological investigations. These will be reported at a later date, but preliminary cytological results indicate that the mouse tumours exhibit typical mouse chromosomes.

NUCLEAR VARIATION BETWEEN DIPLOID ANGIOSPERMS

By Dr. H. REES, F. M. CAMERON, M. H. HAZARIKA and G. H. JONES
Department of Agricultural Botany, University College of Wales, Aberystwyth

Extensive polyploid series in many plant genera, particularly in Angiosperms, testify to the prominence and importance of quantitative variation in nuclear genetic material during the evolution and divergence of numerous species. In sharp contrast, but not uncommonly, are other plant genera which show little or no trace of polyploidy, and are composed of species with consistently diploid chromosome numbers. In these diploid groups it would appear on the face of it that variation in the amount of nuclear material has played little or no part in their divergence and evolution. However, this impression of constancy in nuclear material in the diploids may well be more apparent than real. For example, McLeish[1] has reported a ten-fold difference between the nuclear DNA contents of two diploid *Liliaceous* species and a smaller, though considerable variation between two *Allium* species[2]. The indication is that large changes in the amount of nuclear material may take place quite independently of change in chromosome numbers such as polyploidy. This article is a brief account of a survey of species in *Lathyrus*, *Vicia* and *Lolium*, meant to determine the extent of quantitative variation in nuclear material, particularly in DNA, between diploid species in the three genera. Evidence is also presented which relates to the origin of such variation and, finally, the consequences of such variation in genetical terms are briefly discussed.

Lathyrus

This genus comprises, almost exclusively, diploid species with fourteen chromosomes. Although the chromosome number is constant, there is a considerable variation in chromosome size between species (Fig. 1) and therefore a suggestion of variation in the amount of genetic material. However, a difference in chromosome size cannot with any confidence be assumed to reflect a real difference in mass. Differences in size could reflect merely differences in coiling or even in water content and could be quite independent of the real variation in the content of nuclear material, including DNA. It was thought desirable for this reason to ascertain in the first place whether the size variations were associated with variation in dry mass. For this purpose measurements were made by interference microscopy of the dry mass of isolated 4*C* nuclei in different *Lathyrus* species. These values are plotted against the chromosome volumes of the different species as estimated from measurements of mitotic metaphases (Fig. 2*a*). The volumes were calculated assuming the chromatids to be cylindrical in form, an assumption which, although not necessarily strictly true, is a reasonable enough approximation. Fig. 2*a* shows a clear correlation between chromosome size and mass, and a considerable variation in nuclear dry mass between the related diploids is equally clear. That part of the variation in nuclear dry mass and in chromosome volume is associated with a variation in nuclear DNA is confirmed by nuclear DNA measurements made by Feulgen photometry. Values of 2*C* nuclear DNA are plotted in Fig. 2*b*, against chromosome volume for twelve *Lathyrus* species. Of particular interest is the nuclear DNA variation, by a factor of up to 3·5, between diploid species within this genus. The variation is equivalent to that found between 2*x* and 7*x* in a polyploid series. The evolution of these fourteen-chromosome

DNA measurements by Feulgen photometry in ten nuclei in each of at least two plants in each species. Procedure also applies to the data on *Vicia* and *Lolium*

Lathyrus diploids has certainly not proceeded independently of variation in the amount of nuclear material, including variation in nuclear DNA.

Vicia

Vicia species are nearly all diploids, some with fourteen chromosomes, some with twelve. As in *Lathyrus*, there is a large variation in chromosome size between the species. That these size differences reflect differences in dry mass and in nuclear DNA is confirmed, as in *Lathyrus*, by the interference and photometric measurements respectively, as shown in Figs. 3*a* and 3*b*. Again there is anything but constancy with respect to nuclear mass and DNA between the diploid species. A seven-fold variation in nuclear DNA distinguishes *Vicia sativa* from *Vicia faba*—a variation equivalent to that between $2x$ and $14x$.

Lolium

As in *Lathyrus* and *Vicia* there is a considerable, though lesser, degree of variation in nuclear DNA between the diploid species, all of which have fourteen chromosomes. DNA data for six species are given in Fig. 4. It will be seen that the amounts of nuclear DNA vary by about 30 per cent between species. It will also be observed that the species fall into two distinct groups, inbreeders with the greater amount of DNA which, as would be expected, have larger chromosomes, and outbreeding species with less nuclear DNA and with smaller chromosomes. Whether the relationship between the amount of nuclear DNA and the breeding system is widespread or not can only be determined by further surveys. Certainly the relationship is not universal because no such clear-cut correlation is found in *Lathyrus*. In the meantime we note once again in *Lolium* a large variation in nuclear DNA between related diploids, quite independently of variation in chromosome number.

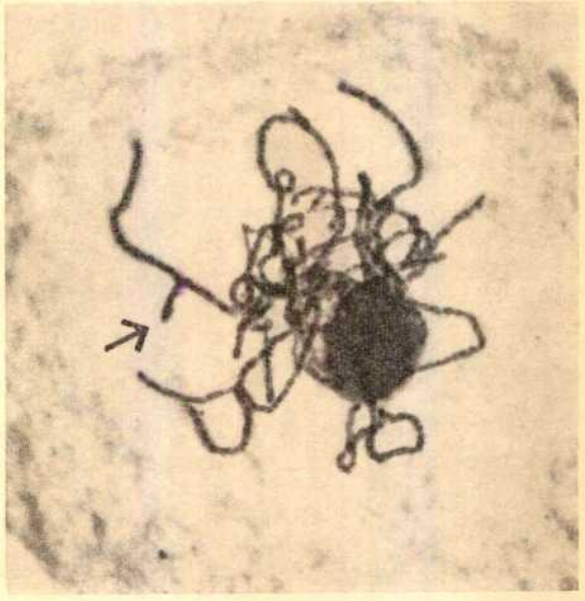

Fig. 5. Pachytene nucleus in a pollen mother cell of *L. perenne* × *L. temulentum*. The loop (arrowed) indicates chromosome duplication

Having established an inconstancy in nuclear DNA between related diploids in a number of genera, the question that immediately arises is by what means the variation originates. The two most likely possibilities are that increase in DNA may arise through (*a*) lengthwise duplication of chromosome segments, that is, an increase in chromosome length, or (*b*) increased polynemy (strandedness) of the chromosomes, that is, an increase in thickness. In genetic terms the distinction between the two possibilities is important. The first implies an increase in map distance and replication of some loci.

The second is achieved independently of change in map distance and by replication of all loci. If lengthwise duplication is responsible we should be able to detect this by the investigation of F_1 hybrids between species with large and small chromosomes and species with large and small amounts of nuclear DNA respectively. At pachytene chromosome duplication in these hybrids should result in loops of the unpaired extra chromosome segments. An investigation of this kind has been carried out in *Lolium* and is briefly described here.

Lolium perenne × *L. temulentum*

L. perenne has smaller chromosomes than *L. temulentum*[3] and, it will be recalled (Fig. 4), the lower nuclear DNA content. The amount of nuclear DNA in the F_1 hybrid is, as would be expected, intermediate between that of the parental species[4]. A pachytene nucleus in a pollen mother cell of the hybrid is shown in Fig. 5. The arrow marks a typical loop. Loops of this kind along with unpaired terminal segments are evidence for chromosome duplication. This evidence does not exclude the possibility of differences in polynemy between the chromosomes of the two species. It does show that in part at least the variation in chromosome size results from the duplication of chromosome segments.

It is evident from these data that a correspondence in chromosome number even between species of the same genus does not necessarily imply a correspondence in the quantity of nuclear material. As we have shown, the quantitative variation in nuclear material, including nuclear DNA, may be enormous. Evidence from *Lolium* shows that at least some of this variation is accounted for by chromosome duplication. Darlington has also pointed out to us that pairing of chromosomes found at meiosis in many haploids is evidence of duplication being widespread among Angiosperm chromosomes. Whether such duplication may entirely account for the nuclear variation in diploids is, however, questionable because of the extent of the variation. Polynemy could also be involved. As yet, however, there is no convincing evidence for it.

It is worth noting[5] that Angiosperm species in general have much higher amounts of nuclear DNA than mammals. So also have *Amphibia*. Whether this implies some difference in the organization or in the function of the nuclear DNA between the different groups remains to be seen.

One surprising feature of our results is the magnitude of the nuclear DNA variation between species of such close genetic relationship. The dipolids *Lolium perenne* and *Lolium temulentum*, for example, are morphologically much alike and, it will be recalled, hybridize quite readily. Moreover, the hybrid between them is fertile to the extent of setting about 12 per cent seed on backcrossing[6]. Evidently variation in the amount of nuclear DNA may not necessarily be directly reflected by variation in phenotype. It may be that much of the nuclear DNA is "uninformative".

Finally, and from a genetical standpoint, one obvious distinction between change in chromosome material associated with polyploidy as compared with that reported independently of polyploidy is that the former is achieved at the expense of increasing the number of linkage groups whereas the latter is achieved without changing the number of linkage groups. The distinction is of importance in relation to the release of variability at meiosis. In this respect alone the distinction may be of adaptive importance.

We thank the Agricultural Research Council for supporting much of this work. One of us (G. H. J.) holds an Agricultural Research Council postgraduate studentship.

DIURNAL VARIATION IN ORGANISMIC RESPONSE TO VERY WEAK GAMMA RADIATION

By PROF. FRANK A. BROWN, JUN., YOUNG H. PARK and JOSEPH R. ZENO
Department of Biological Sciences, Northwestern University, Evanston, Illinois

THERE is widespread agreement that natural background radiation contributes to the observed mutation rate in organisms but to our knowledge there is no evidence that it affects any other biological phenomenon of either animals or plants.

The question of a responsiveness to the natural background radiation is of interest for many reasons. One of these pertains to a possible influence of the radiation on the rates of such fundamental biological activities as, for example, cellular oxidations. The intensity of background radiation not only varies with specific locations over the Earth, but the range from weakest to strongest fields may involve an increase of about a hundred-fold. The average level of basal or standard metabolism or of "spontaneous" activity of an organism could (other things being equal) conceivably reflect differing background intensities. If no such general relationship could be demonstrated, two possibilities would still exist; either there is actually no effect or there is a masking, compensatory biological reaction. A second point of interest bears on a possible contribution of the radiation to the informational input for the geophysically related temporal and spatial organization of the activities of the organism, or the timing system of the biological clock.

It has been reported that the degree of darkening of fiddler crabs relative to appropriate controls is influenced by superimposing lead plates over a wooden cover under which crabs are otherwise shielded[1]. This is presumably a response to increased cosmic ray showers (Rossi effect). Whether increased showers darkened or lightened the crabs varied with a daily rhythm. Darkening occurred at a time of lower metabolic rate and lightening at a time of higher rate with a persistent 24-h rhythm[2,3].

More recently, the orientational responses of planarian worms in very weak caesium-137 gamma fields were investigated[4,5]. It was found that 'north-bound' worms showed what appeared to be a systematic annual variation in direction and amount of turning in response to a field about twice the background presented from the right. The variation included both clockwise and counter-clockwise turning, and paralleled in a striking manner a persistent annual variation in metabolism, or in response to photoperiod, reported for a widely diverse selection of animals and plants[6–10]. These observations suggest that responsiveness to very weak radiation may be related in some way to a geophysically correlated variation in metabolic rate. Not only have persistent annual variations in metabolism been established, but a persistent, poly-

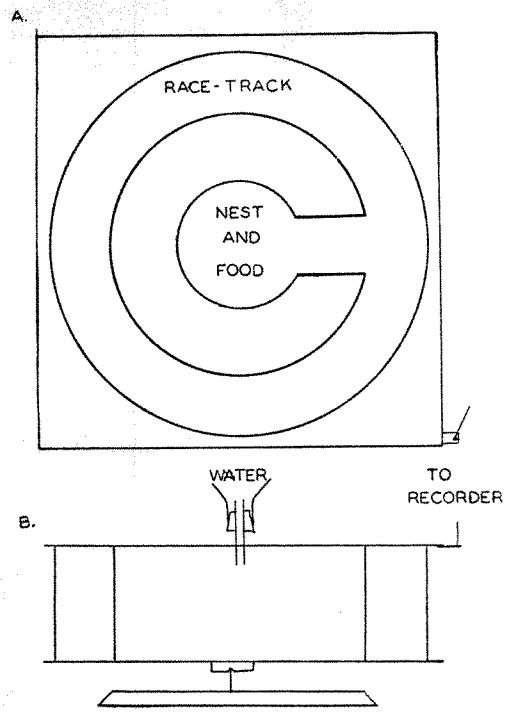

Fig. 1. *A*, Top view of horizontal "race-track" mouse cage. *B*, Side view of same, showing knife-blade pivot and continuous water-supply. For scale dimensions, the outer diameter of the race-track is 8·5 in.

phasic solar-daily pattern of metabolic variation has also been defined, which has a common form in widely different kinds of organism[11].

An experiment was designed to determine: (1) whether small changes in level of radiation have any measurable influence on the overall spontaneity of an organism; (2) whether the characteristic, fundamental 24-h pattern of metabolic variation is reflected in any comparable variation in responsiveness to a very weak radiation field. This article describes and discusses our findings.

The hourly spontaneous activity of four white mice was monitored quantitatively throughout a 3 month period under conditions of alternating periods of one and a half times and about eight times the level of the natural background radiation. To monitor the activity, rocking horizontal "racetrack" actographs were constructed of 0·25 in. screen. The general form of the "track" is shown in Fig. 1. The track was pivoted slightly eccentrically on a knife-edge support so adjusted that there was always tension on a recorder arm irrespective of the location of the mouse in the actograph. Very slight rocking movements produced as the mouse ran around the track were recorded mechanically through a spring-tension system by pen and ink on a moving drum. Two actographs, about 22 in. from centre to centre, were placed on the northern edge of a wooden table (*NE* and *NW*) and the other two were placed the same distance apart on the southern edge (*SE* and *SW*). The two pairs of actographs were separated by about 36 in. The table was situated near the centre of an otherwise unoccupied room illuminated for the duration of the experiment only through windows along the south and west sides. The mice were therefore subjected to day–night changes in illumination and temperature. Food and water were always available in excess. The activity of each mouse for each hour was registered on a 24 h clock driven drum which moved forward 1 cm/h while moving at right angles to the direction of rotation at about 1 cm/day. The latter movement permitted several days of continuous, uninterrupted recording on the same drum. The drum carried millimetre graph paper. In this way the duration of activity was recorded to the nearest 6 min.

A gamma-ray source was prepared which consisted of 24 μc. of caesium 137 deposited on filter paper sandwiched between 'Plexiglass' plates. The activity for all four mice was monitored under conditions in which for alternating periods (usually each of 72 h) the source was placed beneath the table top, first 8 in. below a point centred between the two mice at one end of the table and then below a point centred between the other two mice: when the position of the source was changed, this was done at about 10 a.m. When the γ-ray source was in place it was at an average distance of 13·5 in. from the closest two mice—thus raising the total ambient radiation to about eight times background ("irradiated" or "experimentals")—and at the same time at an average of about 41 in. from the two more distant mice—thus providing an intensity about 1·5 times background ("non-irradiated" or "controls").

A mouse was placed in each of the four actographs on June 18, 1964, and the gamma source was placed at once between the *NE-NW* mice. No data were used until the time of the changeover of the source to the southern end of the table on June 25. This initial period allowed the mice to become accustomed to the apparatus. Thereafter, all mice underwent fourteen periods as controls alternating with the same number of periods as experimentals. Recording finished on September 18.

For each of the twenty-eight periods the average hourly activity was determined for the experimental and control mice. In the course of the experiment one pair of mice acted as a synchronous control for the other pair and a consecutive, alternating control for itself. It was hoped that this method would take into account and compensate for differences in natural spontaneity among the individual four mice. By extending the experiment over a 3 month period, randomization was effected of differences between experimentals and controls which were not synchronous in time; that is, differences arising from variations in daily illumination, temperature, and geophysical phenomena correlated with the weather, time of month, etc. The position of the mice on the table and any differences between the cage recorders were controlled in that all four mice and cage recorders contributed equally to the experimental and control samples.

Each of the four mice showed its own specific mean 24-h pattern of activity for the 3 month period. All, however, showed predominantly nocturnal activity. There was no conspicuous difference between the mean specific detailed patterns for the same individual for the days on which it served as experimental and control. As the variations in environmental temperature and illumination were the same for all four mice, it was clear that the differences between the four mice in their mean daily patterns represented individual peculiarities in response to the same environmental variations. The mean daily pattern of activity for all the control mice is shown in Fig. 2 together with the mean pattern for all the experimental mice. Fig. 3*A* shows the mean daily pattern of

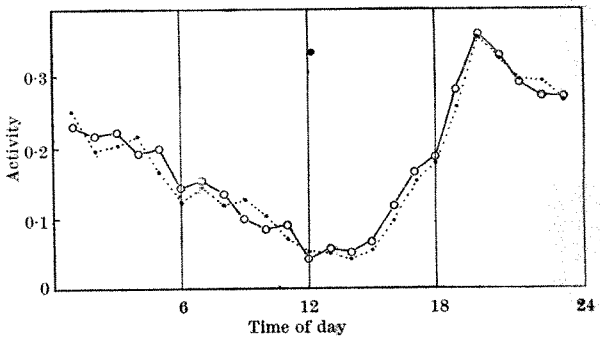

Fig. 2. Mean daily cycle of activity for all four mice during the 3-month investigation while in the higher (broken line) and lower (solid line) gamma fields

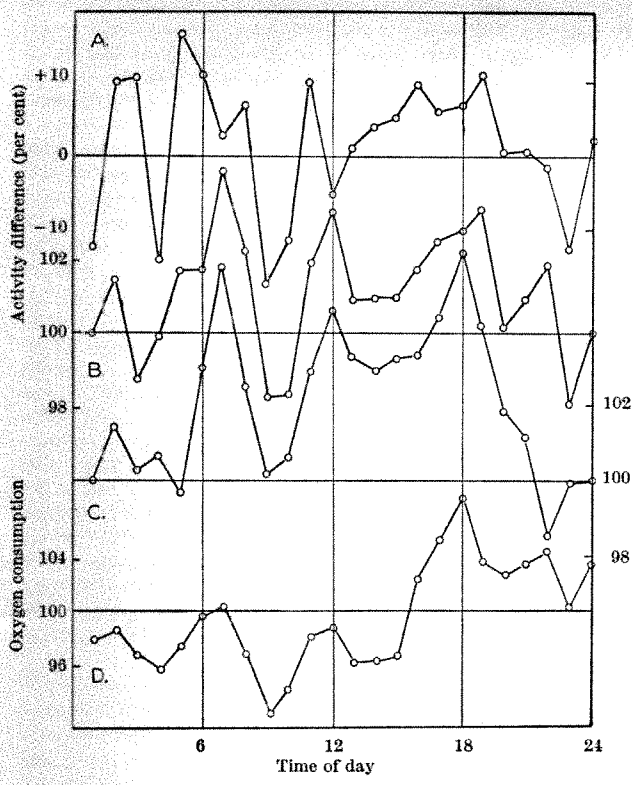

Fig. 3. *A*, Daily variation in activity of the control mice relative to that of mice in the experimentally elevated γ-radiation field compared with oxygen consumption of (*B*) potato, (*C*) carrot and (*D*) mealworm, showing a cycle form which persists in carefully controlled "constant" conditions in widely different kinds of living systems. The variations are expressed as percentage-deviations from either the daily mean rates or of the values from midnight to 1 a.m.

differences between the activity of the controls and experimentals.

The hourly differences are plotted as percentages of the daily mean for all mice. A positive value indicates that the experimental animals were less active than the controls. The mean period of activity per hour was 0·1749 h for the controls and 0·1714 h for the experimentals. Fig. 2 suggests that no statistically significant difference in overall spontaneous activity is likely to exist between the two. The range in the daily variation is very large in comparison with any possible mean influence of the increased radiation. Only further experiments can reveal whether the observed overall 2·0 per cent depression at the higher level of radiation compared with the lower level represents a real, reproducible difference. However, when the mean hourly differences (Fig. 3*A*) were considered a non-parametric χ^2 test showed these to differ from random expectation ($P < 0{\cdot}05$), favouring the side of depression. These hourly differences ranged from an apparent 16·9 per cent depression in activity in response to the higher field relative to the lower one at 5 a.m., to a 17·6 per cent increase at 9 a.m. The distribution of values about zero appeared more like asymmetrical bimodal than a random distribution.

The results of this experiment suggest that the increase or decrease of activity in response to the presence of the higher γ-radiation field depends on the time of day. It is probably not accidental that the apparent daily variation in the response of mice to the higher γ-radiation field should possess a pattern which resembles the persistent, basically polyphasic, daily variation in oxygen consumption which has been reported for many organisms. Examples of such organisms would include potatoes (Fig. 3*B*), beans[7], mealworm larvae[12] (Fig. 3*D*), carrots[11] (Fig. 3*C*), and young chick embryos[13], under constant illumination and at constant temperature. It has been suggested[6,11,14] that this polyphasic daily variation in metabolism is derived as a response of the living system to some mean geophysical cycle or cycles of factors other than those normally controlled in the laboratory.

The 24-h pattern of respiratory variation for potatoes (Fig. 3*B*) is for the 12-month period from February 1, 1964–January 31, 1965, including the period of the present investigation. This same specific daily pattern in the potato has been recorded for 9 consecutive years, with more than a million potato-hours of data. The coefficient of correlation between the consecutive corresponding mean hourly values for the metabolism of potatoes (Fig. 3*B*) and the apparent mouse response to γ-irradiation (Fig. 3*A*) was 0·561 ($t = 3{\cdot}16$; $P < 0{\cdot}005$). The daily variation in mouse response to the weak γ-radiation level is very similar to the geophysically-dependent variation in potato metabolism. Much of the remaining difference between these two daily patterns appears to be a consequence of unexplained variations about a common general cycle-form rather than about zero. This is suggested by the greatly increased similarity which at once becomes evident when 3-h moving means for the two are compared (Fig. 4*A*).

Some earlier results[16] from experiments with rats offered an opportunity to determine whether a deep-seated 24-h variation underlies the circadian rhythm. The mean activity for each clock hour of the day had been determined for a male white rate using hourly data from 58 consecutive days. This specific duration of the experiment was suitable for analysis because it allowed at one and the same time the randomization of a large-amplitude, rather regular, mean 25·25-h circadian cycle which scanned the solar day almost exactly three times and a mean lunar-day variation of rather large amplitude which scanned the day almost exactly twice. The residual 24-h variation, converted as were the mouse data to a 3-h moving mean of percentage deviations from mean hourly activity, is shown in Fig. 4*B*. A general similarity with the cycles of Fig. 4*A* is evident and the cycle shows the maximum at 6–7 a.m. and the broad evening maximum.

Rats and mice, unlike potatoes, beans, carrots, mealworm larvae, and young chick embryos, are organisms

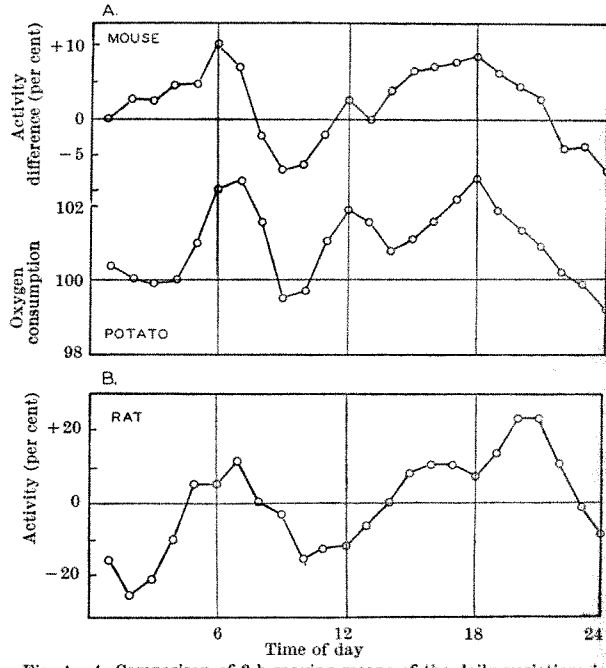

Fig. 4. *A*, Comparison of 3-h moving means of the daily variations in apparent response of the mice to the increased radiation and oxygen consumption in potatoes investigated during the same year. The two relationships were based on more than 4,000 mouse-hours and more than 100,000 potato-hours, respectively. *B*, Mean solar-day variation found to coexist with an overt 25·25 h circadian and a lunar-day variation in a male rat (ref. 16) during 1,392 consecutive hours of activity monitoring in constant low illumination. This was exposed as a residual variation after complete randomization of the other two components

with a conspicuous overt circadian periodicity. Although Fig. 4*A* strongly suggests that a 24-h component of some geophysical activity underlies the observed 24-h circadian variation, Fig. 4*B* suggests that this type of 24-h component underlies a circadian periodism even while, under conditions of constant illumination and temperature, its overt cycles regularly deviate from the 24-h length.

The fact that mice show mean deviations (Fig. 3*A*) for specific hours of the day ranging rather sharply from a stimulation of more than 15 per cent to a depression of the same order, together with the rather nice mean balance between the two over the course of a 24-h period, suggests that the overall relative stability observed under different levels of radiation exists only within the framework of an orderly mean 24-h pattern of variation in responsiveness. As with many other otherwise well regulated physiological phenomena, the overall constancy is invaded by a 24-h variation.

There appears to be a good correlation between the fundamental extrinsically derived, polyphasic 24-h variation in the consumption of oxygen and the response to very weak γ-radiation field, but the results in Fig. 2 show no comparable relationship between the large circadian variation in activity and the response to radiation, despite the far larger range of overall metabolic variation which must be involved. This suggests that variations in other still uncontrolled environmental factors rather than metabolic rate as such are determining the strength and direction of the influence of a very weak field of γ-radiation on the mice. Just as there seem to be specific times of day when a substantial response of one or another sign is present, so conditions may be found naturally, or be created experimentally, in which overall mean influence of small alterations in the radiation fields can be observed even with organisms such as mice.

It seems reasonable to presume that the general polyphasic pattern of daily variation in oxygen consumption found in several widely diverse animals and plants reflects a corresponding pattern of sensitivity to the ambient natural radiation level. This seems especially probable since both field strengths used here lie well within the range of intensities naturally occurring over the Earth's surface.

That sensitivity to background radiation contributes to the temporal organization of the living organism is suggested by the finding that background radiation shows a characteristic mean daily variation with a range of the order of 2 per cent. A statistically significant correlation continuing over several months has been reported between the day-to-day deviations from the mean daily cycle form of oxygen consumption in potatoes with the comparable deviations in the level of background ionizing radiation[15]. It was not established whether the correlation reflected a direct response to the radiation.

Perhaps it is equally significant that a mammal, here the mouse, has a more basic physiological 24-h variation underlying its circadian rhythmic system (Figs. 3*A* and 4*A*). The specific pattern of this variation seems to be shared with a very diverse selection of other animals and plants. It is possible that this variation or a related variation may exist for all terrestrial organisms.

The general similarity of the mean 24-h oscillatory pattern whether measured with actographs or respirometers in organisms with or without overt circadian rhythms points to the existence of a widespread, if not universal, deep-seated solar-day biological variation. Its mean accuracy is evident from its apparent phase-locked relationship to the hour-angle of the Sun. The persistence of this same specific relationship, indicated by the maxima at 6–7 a.m. and in the late afternoon, whether the ambient temperatures are those of a laboratory room or of an arbitrarily set constant-temperature water-bath implies complete independence of temperature. Such a variation could be one of the long-sought temperature- and drug-independent timing oscillations for the biological clocks.

NEPHRECTOMY-POTENTIATED TISSUE CHANGES WITH PARTICULAR REFERENCE TO GLOMERULONEPHRITIS

By Prof. J. GOLDBERG, S. R. GREENBERG and Dr. R. V. MILLISER

Departments of Microbiology and Public Health and Pathology, The Chicago Medical School, Chicago, Illinois

During the course of investigations of renal hyperplasia induced by excision of a kidney, it was noted that rats which had been given anti-normal rat serum rabbit serum (NRSRS) followed by unilateral nephrectomy, showed marked histopathological changes in the kidney which remained. The changes found were: marked swelling of capillary tufts with obliteration of Bowman's space, without evidence of inflammatory cell invasion; marked cortical degeneration; cerebral oedema; after 4 days, mononuclear cell infiltration of the bronchial perivascular areas. This article reports the findings of a series of experiments which extend and confirm these original observations.

Sprague–Dawley rats, each of about 200 g, were fed a standard rat diet and individually caged. The animals were randomly divided into groups as shown in Table 1.

The NRSRS was produced by intravenous injection of rabbits with three 0·1 ml. portions of Sprague–Dawley rat serum per week for 2 weeks. Four days after the final injection, the rabbits were bled by sterile cardiac puncture and the serum tested for anti-rat serum precipitins using a qualitative test. The sera were positive when tested with an antigen dilution (rat serum) of 1 : 10,000.

Table 1. Treatment Groups

(1) Rats receiving 3 ml. normal rabbit serum.
(2) Rats receiving 3 ml. normal rabbit serum and subjected to unilateral nephrectomy.
(3) Rats subjected to unilateral nephrectomy.
(4) Rats receiving 3 ml. of anti-normal rat serum rabbit serum.
(5) Rats receiving 6 ml. of anti-normal rat serum rabbit serum.
(6) Rats subjected to sham operation only.
(7) Rats receiving 3 ml. of anti-normal rat serum rabbit serum and also subjected to sham operation.
(8) Rats receiving 3 ml. of anti-normal rat serum rabbit serum and subjected to unilateral nephrectomy.

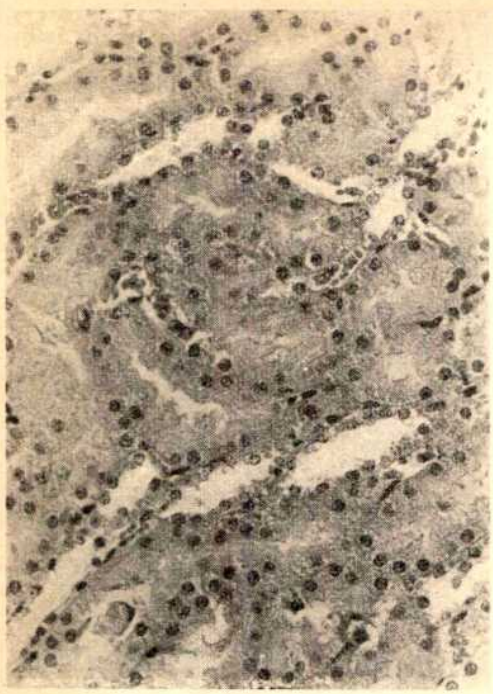

Fig. 1. Section of kidney 24 h after the final serum injection following nephrectomy. Note the cortical tubular degeneration present at this time. (Haematoxylin and eosin, × 220)

Fig. 2. Section of kidney 24 h after the final serum injection. Note the marked degeneration and necrosis of the cortical tubules. (Haematoxylin and eosin, × 50)

Twenty-four and two hours before nephrectomy, each rat received intraperitoneally 1·0 ml. of NRSRS. Under nitrous oxide–ether anaesthesia, the left kidney was removed through a mid-line abdominal incision. The renal vessels were carefully ligated to avoid excess bleeding and the abdominal wall was sutured in layers. Twelve hours after nephrectomy, a third and final injection of 1·0 ml. of NRSRS was given intraperitoneally. Control animals were on a similar time schedule. The rats were killed by decapitation at various time intervals after operation and kidneys, lungs and brains were removed. The tissues were fixed in neutral formalin. Paraffin sections 3–4μ thick were prepared and stained with haematoxylin and eosin, periodic acid–Schiff stain (McManus PAS technique) and the Heidenhain–Azan stain. Kidneys removed at operation were treated in a similar fashion.

The twelve animals that were given NRSRS and nephrectomized showed the following changes: in kidneys removed 12 h after nephrectomy no glomerular changes were noted, although appreciable tubular degeneration was present. The tubular cells were pale, many of the nuclei indistinct; the cell boundaries were often unclear. Twenty-four hours after kidney excision, the capillary tufts were oedematous, but little or no evidence of inflammatory cells could be discerned. There was considerable degeneration of the cortical tubules (Fig. 1), and the cortical vessels were distended. Cortical changes reached a maximum at 48 h. At this time many tubular cells had undergone marked degeneration and necrosis (Fig. 2). The areas affected were pale and cells in such regions had lost their outlines. In some cells, the nuclei were shrunken. At 4 days the cortex began to assume a more normal appearance; the epithelial cells had a recognizable outline and the congestion was reduced. The changes observed in this series are similar to those originally found, except that the glomerular changes tended to be less accentuated. Capillary swelling and mural oedema in afferent arterioles were also observed (Fig. 3). At 24 h, congestion and oedema were also noted in the brain; the perivascular and perineural spaces were widened and the capillaries were dilated (Fig. 4). After 3 days, focal perivascular and interstitial collections of large mononuclear cells, some of which were plasma cells, were noted in the lung associated with the larger pulmonary vessels (Fig. 5). It must be emphasized, however, that all these changes were only observed in rats which had received the serum and undergone nephrectomy. Control animals that had been inoculated only with NRSRS, normal rat serum only, unilaterally nephrectomized only, sham operated only, given twice the amount of NRSRS only, or given normal rabbit serum and

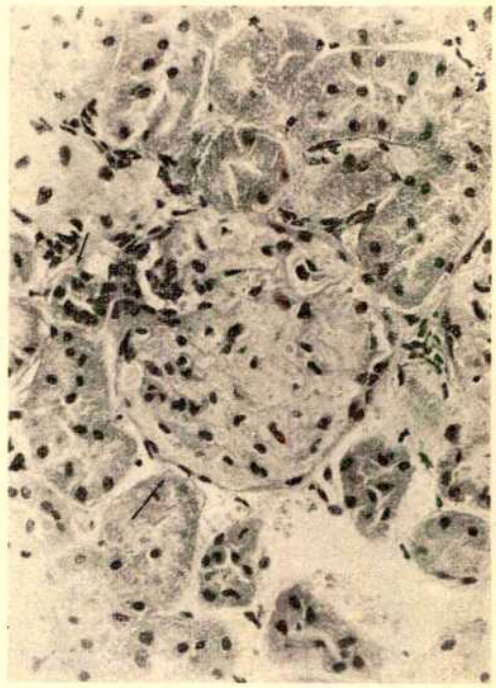

Fig. 3. Section of kidney 24 h after the final serum injection following nephrectomy. Observe the marked swelling of the vascular endothelium of the capillary tuft and afferent arteriole. (Haematoxylin and eosin, × 220)

subjected to unilateral nephrectomy, did not reveal any signs of tissue pathology. It was only when the NRSRS was combined with unilateral nephrectomy that histopathological changes appeared.

In order to substantiate further the histological observations described here, the experiments were repeated and, in addition, an intravenous injection of sterile Evans blue solution was used before nephrectomy. Three millilitres of sterile 2·5 per cent Evans blue in saline were injected into the tail vein of each animal at the time of the second injection of antiserum. The animals were killed after 12, 24, 48, 72 h, 4 and 5 days and the tissues observed grossly. Only in those rats subjected to unilateral nephrectomy and NRSRS were changes in vascular permeability found. At 24 h to 4 days the Evans blue dye was observed at the renal corticomedullary junction; staining was intense at 24 h but tending to be reduced at later periods. No dye was observed at 12 h or at 5 days. In addition, in three of the animals the dye was noted in the sclera and in the tracheal cartilages. We wish to emphasize that rats under other treatment régimes exhibited no extravasation of dye. The results are summarized in Table 2.

These results indicate that only the combination of nephrectomy and antiserum initiates these vascular changes. It may also be pointed out that the histopathological changes in the kidney closely parallel the transudative changes observed with the Evans blue technique.

From the results obtained we can assume that the occurrence of the pathological changes described arises from the simultaneous presence of two factors, one contributed by the injection of antibody directed against the normal host component and the other contributed by the unilateral nephrectomy. Although it has not yet been shown, it is reasonable to assume that the injection of anti-NRSRS results in the production of circulating antigen–antibody complexes, which are probably soluble, as such complexes could be assumed to be in antigen excess. (Since this article was originally prepared, we have obtained essentially identical results using washed rat serum-NRSRS precipitate as a substitute for the NRSRS.) The presence of these complexes by themselves

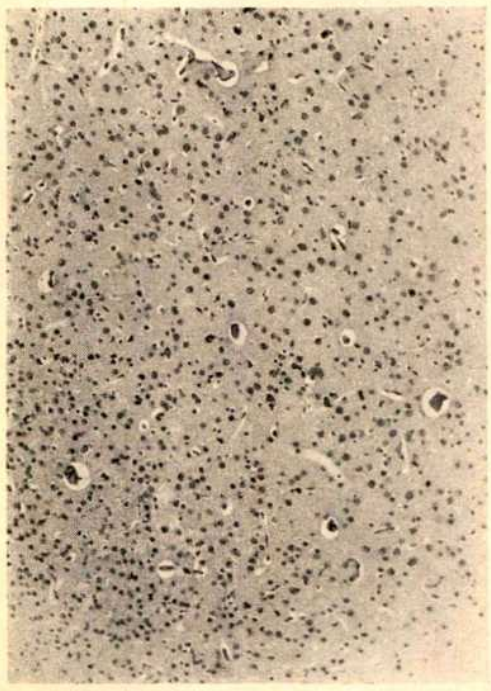

Fig. 4. Section of cerebral cortex 24 h after the final serum injection following nephrectomy. The widening of the perivascular and perineuronal spaces is illustrated. (Haematoxylin and eosin, × 50)

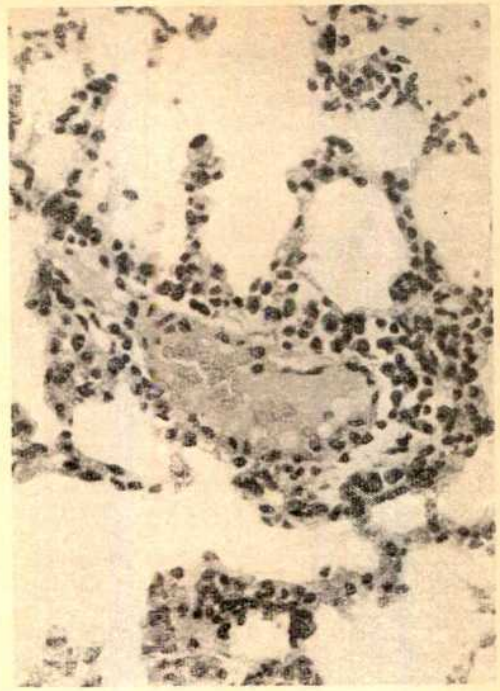

Fig. 5. Section of lung 4 days after the final serum injection following nephrectomy. A collection of mononuclear cells around a vessel is shown. (Haematoxylin and eosin, × 50)

is not sufficiently active to produce histopathological changes. The effect of the second factor may result from unilateral nephrectomy, for this procedure has been shown to have a direct effect on the production of hyperplasia in the contralateral kidney[1,2], and serum from a nephrectomized animal may be passively transferred and exert a hyperplastic effect[3]. Argyris and Trimble[4] have demonstrated that damage to the mouse kidney, such as by multiple needle insertion, results in the appearance of increased mitotic activity in the contralateral organ—which is another indication of humoral transfer.

The result of nephrectomy cannot be considered to be merely mechanical, for if the effect of nephrectomy were merely to change the ratio of kidney surface to circulating fluids, then it might be assumed that twice the concentration of serum antibodies should have the same effect on a non-nephrectomized animal. This was shown not to occur.

It may be postulated that the presence of these two factors in the host initiates a series of activities which produces changes in the vascular permeability which then

Table 2. EFFECT ON RAT OF UNILATERAL NEPHRECTOMY COMBINED WITH ADMINISTRATION OF ANTI-NORMAL RAT SERUM RABBIT SERUM

Treatment of rat	Histopathology noted in contralateral kidney	Changes noted in vascular permeability (Evans blue technique)
Normal rabbit serum 3 × 1 ml.	None	None
Normal rabbit serum plus nephrectomy	None	None
Sham operation	None	None
Sham operation anti-normal rat serum rabbit serum	None	Not done
Anti-normal rat serum rabbit serum 3 × 1 ml.	None	None
Anti-normal rat serum rabbit serum 3 × 2 ml.	None	Not done
Unilateral nephrectomy	None	None
Anti-normal rat serum rabbit serum 3 × 1 ml. plus unilateral nephrectomy	Kidney tubular degeneration glomerular swelling, capillary dilatation: cerebral oedema and mononuclear infiltration of lung	Dye noted in corticomedullary junction and medulla of sclera of 3/12 rats

results in histological renal alterations interpreted as glomerulonephritis.

These results also indicate that the effects of the changes are not localized to the kidney. It may well be that the action is on the vascular system in other areas of the body such that it changes the permeability of the vascular bed, and thus allows transudation to occur in many areas. An illustration of this may be the marked capillary dilatation and oedematous reaction in the brain. We believe the reaction in the lung is secondary and that the focal collection of large mononuclear cells may have a phagocytic action. It is noteworthy that the cells were not observed until three to four days after injection, well after the period of time when renal changes were noted.

TRANSFER OF METABOLIC ENERGY TO SODIUM

By DR. EDWARD S. HYMAN
Touro Research Institute, New Orleans, Louisiana

MANY living membranes can bring about a net flow of sodium from a dilute solution on one surface to a more concentrated solution on the other surface. Somewhere within this membrane the activity, or energy, of sodium must be reversibly raised to exceed that of the recipient solution in order that sodium will flow against the overall gradient.

It is not possible rigidly to quantify the activity or any other parameter of the energy of an individual ionic species. However, measurements can be made that will give comparative values in solutions that are nearly alike. Errors are lessened when estimates by one method are confirmed by a second method using different assumptions. *p*H measurement is an example of this type of measurement, and ΔpH is an estimate of a difference in hydrogen ion activity, a parameter of energy. In the course of an investigation of an analogous concept for sodium[1], observations on one series of salts stand out as unique in their implications, although not unique in the pattern for sodium salts. Because adenosine triphosphate (ATP) participates in sodium metabolism, its relationship to relative sodium activity deserves special mention.

ATP is a substituted tripolyphosphate with the fifth valence involved as an ester to ribose. Thus sodium in Na_4ATP may be expected to resemble sodium in salts of the sodium tripolyphosphate family. Sodium ATP differs from sodium pyrophosphate in that the pK_4 of sodium ATP is near *p*H 7·0 (*pK* is a function of ionic strength and of the specific cation). In essential metabolism ATP hydrolyses to the diphosphate (ADP), a substituted pyrophosphate, with the liberation of about 9,000 cal/mol. The ADP anion has a maximum charge of −3, and its 0·1 N sodium salt has a pK_3 at *p*H 6·51, compared with *p*H 6·68 for 0·1 N $Na_{3\cdot5}$ ATP. The terminal phosphorus which is split off appears as orthophosphate, either free, as an ester, or as an amide.

The activity per unit concentration or activity coefficient for sodium (γ^+_{Na}) may be expected to follow roughly an expression of the Debye–Hückel equation, for example,

$$\text{Log } \gamma^+_{Na} = -\frac{0{\cdot}523\sqrt{\mu}}{1+\sqrt{\mu}} \text{ at } 37^\circ \text{ C}$$

where μ is the ionic strength. For sodium salts at the same normality, μ increases with anion valence in the relationship $\mu = \frac{1}{2}$ (1 + anion valence) × normality. Hydrolysis of ATP^{-4} or of $ATP^{-3\cdot5}$ to anions of lower valence without a change in normality also results in a lowering of ionic strength. Sodium activity would be expected to rise.

Table 1. PERCENTAGE OF SODIUM BOUND AS ESTIMATED FROM CONDUCTANCE AND TRANSFERENCE

(*a*) ATP family

Normality	$Na_4P_2O_7$	Na_4ATP	$Na_{3\cdot5}ATP$	Na_3ADP	$Na_{2\cdot5}ADP$	NaH_2PO_4

0·1	24·9	22·8	19·5	15·0	12·3	2·2
0·03	18·7	16·8	13·6	10·6	8·5	1·1
0·01	12·3	10·6	11·9	7·1	5·2	0·5
0·003	8·9	7·9	6·9	5·4	2·6	–

(*b*) Mixtures and complexes

Normality	$Na_{3\cdot5}$(ADP + P)	Na_2MgATP	NaMgADP
0·1	12·1	12·8	8·0
0·03	9·0	6·8	

Estimates of γ^+_{Na} in this series of salts using a sodium-sensitive glass electrode and a reference electrode with liquid junction[2] are shown in Fig. 1. It was assumed that $\gamma^+ = \gamma^- = \gamma^\pm$ in sodium chloride. The glass electrode was checked against a sodium amalgam electrode to eliminate the possibility of an artefact of the glass resulting from anion sensitivity. The curves for log γ^+_{Na} fall progressively below the Debye–Hückel limiting slope (*S*) in the order of increasing anion valence.

This separation of curves is due to ion binding which increases with anion charge. The ion binding is similar to that reported by Wall and Doremus[3] for the non-esterified pyrophosphate and tripolyphosphate. Application of their method[4], involving conductance and transference, gave the results shown in Table 1. The bound fraction is almost a linear function of anion charge at any normality, and is roughly a parabolic function of the square root of the normality at any valence. The data may be approximated by the empirical set of parabolas $B = 12{\cdot}5\ (V-1)\ N^{\frac{1}{2}}$ in which B is the bound fraction, V the numerical value of the anion valence and N the normality. By potentiometry and by conductance-

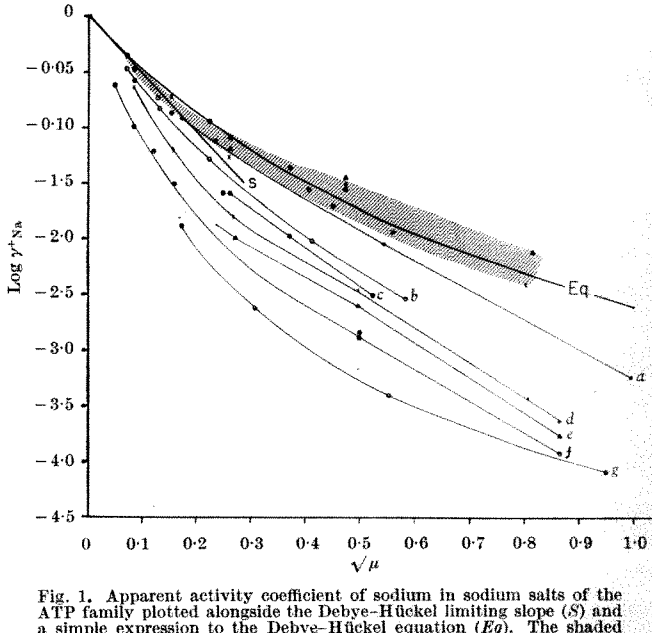

Fig. 1. Apparent activity coefficient of sodium in sodium salts of the ATP family plotted alongside the Debye–Hückel limiting slope (*S*) and a simple expression to the Debye–Hückel equation (*Eq*). The shaded area contains points from the same potentiometric data recalculated for the free fraction of sodium by conductance-transference or extrapolated by the equation for the bound fraction. *a*, NaH_2PO_4; *b*, $Na_{2\cdot5}ADP$; *c*, Na_3ADP; *d*, $Na_{3\cdot5}ATP$; *e*, Na_4ATP; *f*, $Na_4P_2O_7$; *g*, $Na_5P_3O_{10}$

transference, more sodium is bound by $P_2O_7^{-4}$ than by ATP^{-4}, perhaps because of the more concentrated charge of the $P_2O_7^{-4}$. (The data for non-esterified pyrophosphate may be fitted to the surface generated by arbitrarily assigning an extra half charge.) Recalculation of γ^+_{Na} based on the concentration of unbound sodium results in mapping of the curves into the shaded area in Fig. 1. This area contains the curve (*Eq*) of the Debye–Hückel equation given above and approaches the Debye–Hückel limiting slope (*S*) from above as expected for fully dissociated salts. Thus the magnitudes of the bound fractions as estimated by two methods are comparable, and relative values for γ^+_{Na} are rational. These data show that hydrolysis of ATP will release a significant portion of the bound sodium fraction.

The partial stoichiometric equation for the reaction involving the 3·5 salt may be written,

$$Na_{3\cdot5}ATP \rightleftharpoons Na_{3\cdot5}\,(ADP + P)$$

In Fig. 2, estimates of γ^+_{Na} of the left and right sides of the equation are plotted against the molarity of the sodium because that is a fixed quantity. Separation of these curves includes both the effect of a change in μ and a change in the bound fraction. At 0·1 N the rise in sodium activity is about 22 per cent, which would require about 110 cal/mol. This may be regarded as a transfer to sodium of a fraction of the energy liberated in hydrolysis.

Enzymatic hydrolysis probably involves the stable mono-magnesium complex. The corresponding salts are Na_2MgATP and NaMgADP, which are essentially 1:2 and 1:1 salts. The same mechanism holds. Estimates of γ^+_{Na} for these salts and for an equimolar mixture of NaMgADP with NaH_2PO_4 (the hydrolysis products) are shown in Fig. 3. Estimates of bound sodium are again given in Table 1.

This relationship uniquely fits the notion of the sodium pump. At a given temperature and normality, γ^+_{Na} may be affected only by a change in the medium or a change in anion distribution. The constant (0·523) in the Debye–Hückel equation includes the dielectric constant of the medium. It has been found that to change sodium activity reversibly by altering the medium, by adding uncharged or dipolar substances, requires large additions because the solvent water is 55 molar. A change by altering the distribution of anion charges is theoretically more suitable for the task. Hydrolysis of ATP is the most prominent instance of such change. (The addition of an equal number of moles of a strong monobasic acid to $Na_{3\cdot5}ATP$ would result in a similar reduction in ionic strength and in ion binding, but would result in a much lower *p*H. The pK_3 of sodium ATP is about *p*H 4·4 compared with the value of *p*H 6·2 on the right side of the equation.) The enzyme ATPase is present in cell membranes[5], and the hydrolysis of ATP is believed to occur there. This

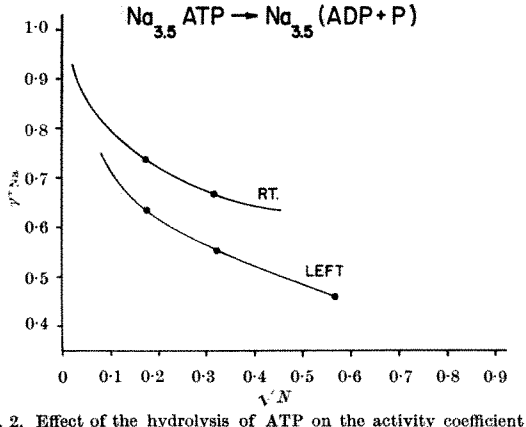

Fig. 2. Effect of the hydrolysis of ATP on the activity coefficient for sodium. The abscissa is the square root of the normality so as to include the effect of a change in ionic strength

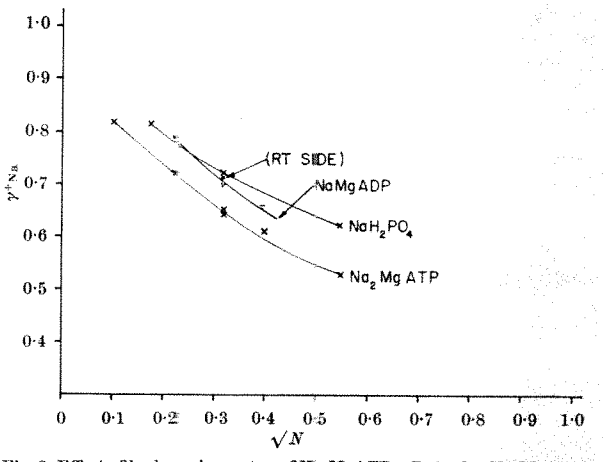

Fig. 3. Effect of hydrolysis on γ^+_{Na} of Na_2MgATP. Data for Na_2MgATP, NaMgADP, NaH_2PO_4 and Na_2(MgADP + P) are plotted against the square root of the normality to include the effect of ionic strength

enzymatic hydrolysis of ATP is affected by digitalis and by other agents which affect the transport of sodium across the membrane *in vivo*. Thus the rise in sodium activity described provides the most reasonable explanation for the rise in ion activity which is necessary to pump sodium against a gradient.

The transfer of energy to sodium is obligatory. The quantitation in a water medium is only approximate. Teleologically, the reaction appears wasteful. In a medium of lower dielectric constant, perhaps a cell membrane, the rise in γ^+_{Na} should be greater. Cation selectivity is unlikely unless it is conferred by the medium or by an intermediate. However, directional flow requires a gating device. Large gradients could also be created by gating between stages, for example, by means of the less polar end of the ATP molecule as it is oriented on the enzyme. (In this instance these anions would not move at random. Nevertheless the effect on sodium would be similar because γ^+_{Na} is still a function of the nearness of anion sites when these sites are fixed to a structural matrix[6]. The inorganic phosphorus or some intermediate would be free of the structure.)

There are other consequences. If sodium is the only permeable cation present, the Donnan potential[6] across a semi-permeable membrane is almost equal to $K\,\Delta\log Na$ activity. This is the nature of the electrode data presented. A rise in γ^+_{Na} and the accompanying rise in hydrogen ion activity necessarily affect the potential across a living membrane which is permeable to both species. Should this rise be a periodic or a triggered function, changes in membrane potential such as the electrocardiogram and the transmitted impulse would then be generated. Large electromotive forces, even that of the electric eel, could be created by a series of cells, each deriving electrical energy from this hydrolysis.

To sum up, by potentiometry, conductance and transference sodium activity rises with the exothermic hydrolysis of sodium adenosine triphosphate, or its mono-magnesium salt, because ionic strength and ion association are both lowered. This hydrolysis is associated with *in vivo* sodium transport against a gradient. The rise in sodium activity suggests a sodium pump analogous to the heat pump.

This investigation was supported by grants from the U.S. National Institutes of Health and the American Heart Association.

ASTRONOMY

Correlation between Peculiar Galaxies and Radio Sources

ARP has claimed[1] that more peculiar galaxies than can be statistically expected lie about midway along lines joining close pairs of radio sources. We have investigated the significance of these claims and, although we have found that the observed distribution might occur by chance in only one sky out of a hundred, we nevertheless believe that much of the correlation is caused by (i) observational selection; (ii) non-uniform large-scale distribution of galaxies and radio sources; (iii) normal clustering of galaxies, radio and peculiar included. The importance of the last two points is emphasized by the fact that bright radio sources occur preferentially in regions of the sky with a high density of galaxies[2].

We investigated the correlation between two classes of objects, population A (usually a class of peculiar galaxy) and population B (usually $3C$ radio sources) by plotting them on a sphere. The angular distances from each member of A to the two nearest members of B were measured. For purposes of comparison, a control population was constructed by moving population A one hour back in R.A. and the measurements were then repeated. Members of A either in or moving into the galactic zone of avoidance, $|b^{II}| < 15°$, were omitted and the survey was limited to the northern hemisphere. The positions of the objects were taken from the catalogues[3–5].

On the basis of Arp's claims we defined a "pair" to have an A to B separation less than 2·2° and a "triplet" to have an A to second-nearest B separation less than 4·5°. χ^2 tests were conducted on four-fold tables of real, comparison (control), "paired" and "non-paired", and Student's t tests on the mean of the distances from each A to the nearest B. These tested whether the number of real pairs was significantly different from the number of pairs in the control. When an entry in the table was less than 10, the χ^2 test was abandoned in favour of an exact probability test. To test for collinearity of the triplets, the internal angle θ between lines joining the peculiar galaxy to the two nearest radio sources was measured. For the most compact triplets a Student's t test was conducted on the means of $\theta°$ and $|90–\theta°|$ to test for significant deviations from 90° and 45° respectively. None was found.

In Table 1, the sixth column gives the probability from the χ^2 test that a correlation greater than or equal to that obtained is due to chance. An attempt to allow for effect (ii) altered this probability to that given in the tenth column.

The correction for effect (ii) was made by recalculating χ^2 with allowance for the hourly distributions in R.A. of both populations, for the real, and control results. The null hypothesis was made that the number of pairs in each hour R.A. is proportional to the product of the numbers of populations A and B in that hour. The numbers of paired and non-paired members of population A expected on this basis were then used to evaluate the corrected χ^2. These so derived give much less significant probabilities. Similar corrections produced similar results for Student's t-test.

In discussing the results it should be stated that we are not convinced that we have removed all effects arising from (ii) and have made no allowance for (i) and (iii); borderline significance (2–5 per cent) is thus not convincing.

The correlation between peculiar galaxies numbered 102–145 in Arp's catalogue and quasars is based on small numbers and is sensitive to the precise separation used to define a pair. There is a marginally significant correlation between all Arp's peculiar galaxies and radio sources, and a more significant one between Arp's special galaxies (Nos. 102–145) and radio sources (about the 1 per cent level). Unfortunately, we were unable to investigate the normal clustering effects fully but, from the photographs in Arp's catalogue, it appears that Arp's specials are more often in clusters than members of his other groups.

In conclusion (i) the evidence for correlation or non-correlation between quasars and peculiar galaxies is inconclusive; (ii) there is no evidence that triplets are approximately collinear; (iii) evidence for real correlation between peculiar galaxies and radio sources is weak. We will have over-estimated the significance of the deviation from chance by neglecting the internal clustering of each species, for example, peculiar galaxies are clustered; thus the effective population is smaller and the value of deduced χ^2 should be decreased.

	27 closest triplets (omitting quasars)					Student's t on $\theta°$	90·0	Student's t on $90–\theta$	30·0	Insignificant	

*VV*1, Vorontsov-Velyaminov Tables 11–16 inclusive; *VV*2, Vorontsov-Velyaminov Tables 5–8 inclusive; *OQ*, omitting quasars; 3*C*, radio sources in ref. 5 (all, unless qualified); 3*CN*, 3*C* "*N*" type galaxies only.

* Pairs defined to have an angular separation less than 4·5° (so chosen in order to obtain sufficient numbers for tests).

† There is an automatic bias in our method when populations A and B are identical.

If there is a surviving correlation, a possible interpretation would be that clusters containing an Arp special galaxy are more likely to be of such an age or density that radio outbursts are more frequent than in average clusters. Some of the triplets are indeed in the directions of prominent clusters of galaxies. We thank Dr. Arp for his comments on this paper.

PHYSICS

Far Infra-red Spectroscopy at High Pressures

PRESSURES sufficiently high to give significant distortion to crystal lattices or dense amorphous systems have been used in combination with spectroscopic observation for some years. The efforts of Drickamer *et al.*[1] have been conspicuously successful in this field but their spectroscopy has been in the ultra-violet, visible and near infra-red regions where the primary transitions are electronic. We have developed a new technique in which very high pressures are combined with far infra-red spectroscopy where absorption by lattice modes dominates, providing useful information about intermolecular interactions. Wilkinson and Sherman[2] have made a beginning in this field by making studies on alkali halides used as the pressure transmitting media in Drickamer's techniques. However, in this article we describe methods which are of general purpose in the sense that the transmission of the system allows features at any far infra-red wavelength to be studied. The new technique is complementary to X-ray studies under pressure in that information can be obtained about the changes of intermolecular forces with changing lattice parameters and crystal structure.

The main experimental problem in this research is to reconcile the conflicting requirements of high radiation transmission through the sample and maintenance of adequate mechanical strength to support the stresses used to create the pressures. The high radiation efficiency of interferometric spectroscopy is turned to advantage to obtain a workable solution. Two types of high pressure apparatus have been used—a six anvil cube type capable of containing pressures up to 35 kbars and a hydraulic type usable up to 12 kbars.

To demonstrate the effectiveness of the new techniques we have examined the effect of pressure on chlorobenzene. The reason for the choice is found in the results of some earlier far infra-red work where it was shown that liquid chlorobenzene has a well-marked isolated band which can be attributed to an intermolecular vibration[3]. The absorption resulting from this might well be expected to be strongly affected by changing the distances between molecules as is indeed the case. In addition to the study of a liquid derived from a dipolar molecule we have studied liquid carbon disulphide the constituent molecules of which have a large quadrupole moment.

Cube anvil device. This is an adaptation of the National Bureau of Standards (Washington) "six anvil high pressure apparatus"[4]. Two opposite anvils have $f/10$ apertures terminating in 0·1 in. diameter holes at the square faces. The latter are sealed by single crystal quartz disks with the optic axis perpendicular to the plane faces. This particular arrangement was found to give the greatest strength. The quartz windows were transparent at frequencies lower than 200 cm^{-1} except for an absorption band at 125 cm^{-1} The transmitted radiation was analysed by a Michelson interferometer[5]. With an acceptable signal to noise ratio, spectra from 10–200 cm^{-1} with resolution 4 cm^{-1} were obtained. Direct absolute intensity measurements could not be made in this device with the same precision as those in the hydraulic device because of variation in the movement of the anvils with increasing load. Reasonable corrections can be made, however, where thick samples and thin windows are used.

Absorption experiments were carried out under pressure on liquid and solid forms of chlorobenzene and carbon disulphide. The high pressure cell was constructed by enclosing the liquids inside a thin walled aluminium cylinder which was sealed at each end by the quartz windows, sample thicknesses being of the order of 0·5–1·5 mm. Pressure calibrations are made by a small manganin wire resistance gauge and by the resistance discontinuity in bismuth at 25·7 kbars. In order to study different solid phases in chlorobenzene a means of producing temperatures greater than 200° C was necessary. A graphite sleeve heater was incorporated, therefore, in the

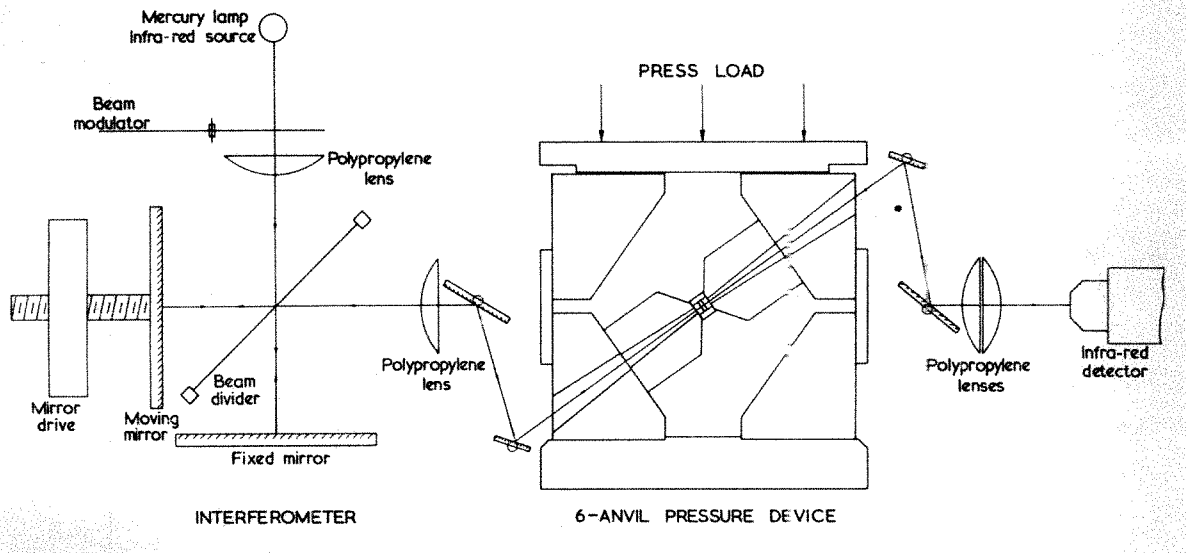

Fig. 1. High pressure six anvil cube device and Michelson interferometer

cube assembly and temperatures were measured by means of a thermocouple.

Hydrostatic piston and cylinder device. This apparatus is an adaptation of a similar one developed by Drickamer[6], although in this case larger apertures were used. The apparatus is not capable of reaching the pressures that can be obtained in the cube anvil device but has a number of advantages within its range: (1) a reduction in the time taken to obtain spectra of given resolution because larger apertures ($f/2$) and windows (0·25 in. diameter) are used, thus increasing the amount of transmitted radiation; (2) pressure measurement is more convenient in the larger sample volume because a manganin wire gauge can be used during a run; (3) the positions of the windows are continuously adjustable and thus the sample thickness can be varied over quite a wide range.

We have recently obtained some new results for the far infra-red absorption spectra of solid and liquid chlorobenzene and carbon disulphide up to pressures of 35 kbars. The absorption spectrum of liquid chlorobenzene was determined with the particular view of improving the understanding of the "pseudo-lattice" absorption mechanism found in many polar liquids. Fig. 2 illustrates values for α, the absorption coefficient as a function of frequency and applied hydrostatic pressure. The point at 29·7 cm^{-1} was determined at atmospheric pressure with a CN maser[2]. The internal consistency between different runs with the high-pressure hydraulic cell was ± 5 per cent. The significance of these results will be discussed on a later occasion.

Bridgman[7] has shown from volume pressure measurements that two solid forms of chlorobenzene are stable under a range of pressures at room temperature (20° C). The liquid freezes to solid I at -50° C under one atmosphere pressure and about 5 kbars pressure is necessary to retain the phase at 20° C. If the pressure is then raised to 15–20 kbars and the temperature raised to 250° C for a few minutes before returning to room temperature, a second solid form is obtained. The two spectra shown in Fig. 2 confirm the existence of these two solid forms.

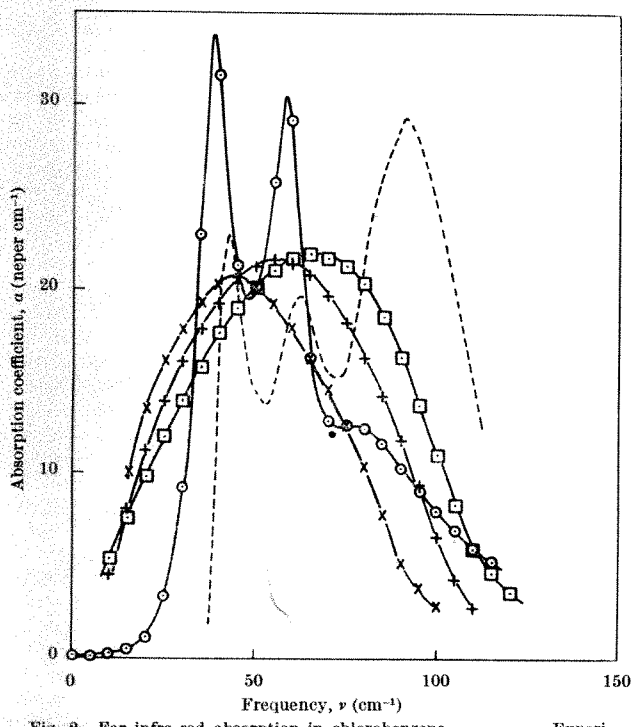

Fig. 2. Far infra-red absorption in chlorobenzene. ————, Experiments with hydraulic device; – – – – –, experiments with six anvil cube device. Liquid: ×, 0·6 kbars; +, 2·3 kbars; □, 4·4 kbars. Solid I, 5·0 kbars (○); solid II, 20 kbars (– – –). Temperature, 20° C

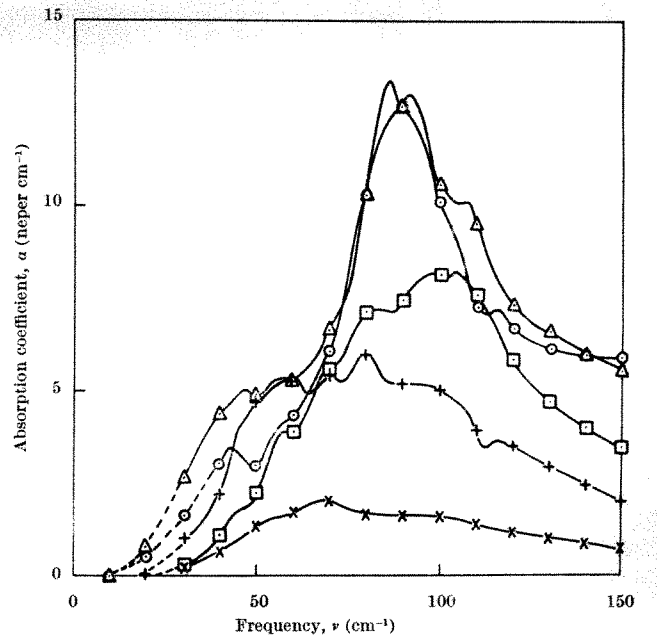

Fig. 3. Far infra-red absorption in carbon disulphide. ————, Experiments with six anvil cube device. Liquid: ×, 1 atm.; +, 3 kbars; □, 11·6 kbars. Solid: ○, 12·0 kbars; △, 12·7 kbars. Temperature, 20° C

Increasing the pressure to 35 kbars has only a small effect on the spectrum, the absorption features moving to slightly higher frequencies.

Carbon disulphide can be frozen at room temperature with a pressure of 12–13 kbars. It appears from the spectra shown in Fig. 3 that there is a very considerable increase in the total absorption up to and through this phase change, which cannot be simply explained by uncertainties in sample thickness and polycrystalline scattering. Even allowing for the 20 per cent greater compressibility of carbon disulphide pressure evidently has a much greater effect on the molecular interactions of quadrupolar carbon disulphide compared with dipolar chlorobenzene.

Surface Wave Velocity Measurement

I have found[1] that surface wave velocities can be conveniently and accurately derived by measuring a critical angle at which, when an ultrasonic beam is reflected from a solid surface in a water bath, there is a violent change in the waveform of the reflected wave train. This occurs when the surface wave velocity and the wave velocity in the water are related by way of Snell's law for an angle of refraction of 90°. Although the indication is accurate and has proved valuable for elasticity measurement, the reason for this behaviour has not been entirely clear.

The transfer of the wave from the water, with acoustic impedance $1{\cdot}5 \times 10^5$ for a 1 cm² beam, is to a thin surface film of the solid—the surface wave only penetrates about one wavelength. At 5 Mc/s this would be about 0·5 mm and the acoustic impedance would be about 10^5, that is, lower than that of the water. In the neighbourhood of the angle at which the wave conversion occurs most efficiently, therefore, a phase change of about 180° occurs and this affects the reflected wave too. Because the waves used in this experiment are not plane waves, the incident beam can be considered to be partly of an angle of incidence greater than the mean angle and partly at a smaller angle. The extent of this effect can be deduced from the angle of lag of the radiation in the appropriate circumstances as calculated by, for example, Goodwin and myself[2]. It is thus possible, when such a beam encounters a solid surface in water, that one part of the beam produces a surface wave of one phase and the other another surface wave 180° out of the phase and that partial cancellation occurs. This leads to a reduction in the amplitude of the reflected wave and this is used as already outlined to determine surface wave velocity.

Figs. 1–3. Argon plasmas in 5 cm diameter torch. Fig. 1. High frequency (3·8 Mc/s). Fig. 2. Dual frequency (3·8 Mc/s and 280 kc/s). Fig. 3. Low frequency (280 Kc/s)

Devices utilizing this principle have been used[3] to investigate the elasticity of single crystals and that of elastically anisotropic polycrystalline aggregates both in bulk form and in sheets. Furthermore, the method of measurement has proved to be of value[4] in investigations of surface stresses (it enables third order elastic constants to be determined); there are also signs that the method can be used to show up incipient fatigue in a non-destructive manner before a crack actually develops.

In the past the two devices which have been developed to investigate this phenomenon have been rather complicated and difficult to construct, but new much simpler forms have now been evolved. In these a single transducer acting as combined transmitter/receiver produces a beam which is first reflected from the surface under examination, then again, but at normal incidence this time from an acoustic mirror (an air-backed thin film), then back to the specimen again and thence to the original ultrasonic transducer now operating as a receiving transducer. An ordinary ultrasonic flaw detector can often be used in this way.

It is believed that this simplification will encourage the use of these devices (one form[3] of which does not need a water bath) both in research and also in industry.

Radiofrequency-induced Gas Plasma at 250–300 kc/s

INDUCED plasmas in static gases at atmospheric pressure were first reported by Babat[1]. A plasma torch based on inductive coupling between a radiofrequency field and a flowing, ionized gas was developed by Reed[2] and later by Reboux[3], Mironer and Hushfar[4] and Marynowski and Munroe[5]. In all cases, the frequencies used were in the megacycle range.

Because the "skin thickness" for radiofrequency heating increases with a decrease in frequency, the use of a lower frequency can be expected to produce a larger plasma with a more uniform temperature. Reed[6] states that attempts to initiate a plasma at 400 kc/s were unsuccessful, and similar results have been reported by Radyne, Ltd.[7], with a 100 kW, high impedance output generator. However, Reed[6] has pointed out that "starting a plasma is a separate problem from running it after it is started", and Dymshits and Koretskii[8] have recently described induced plasmas operating at frequencies as low as 290 kc/s. The latter authors gave only limited experimental details, but appear to have initiated the plasma by temporarily reducing the pressure.

We have used an alternative method of initiation in which a pilot plasma was established in the megacycle range and power was then coupled into this plasma from a second work coil energized at 280 kc/s. Experiments were carried out in a simple quartz-glass torch similar in principle to that described by Reed[6] but with an outside diameter of 5 cm and two tangential gas inlets. The two radiofrequency generators used were not designed for plasma work, but were readily available in the same laboratory and were of appropriate frequency ranges. They were: (1) Radyne *C155/SR*, nominal output power rating 15 kW, nominal frequency 4 Mc/s; work coil four turns, 6·5 cm internal diameter, 3·5 cm long. (2) Thermionic 500, nominal output power rating 20 kW, nominal frequency 375 kc/s. The output from this generator was stepped down by means of a 22 : 5 transformer in order to provide a suitably high inductance load with a practicable size of work coil. The optimum work coil was found by experiment to be eight turns, 5 cm internal diameter, 7·0 cm long. This was situated so that its upper end was 4–5 cm below the lower end of the Radyne work coil.

An argon plasma was initiated at a gas flow rate of about 60 l./min, by lowering a graphite rod into the upper (3·8 Mc/s) field and applying maximum power from generator No. 1. When the lower coil was energized (280 kc/s), the plasma spread down the torch into the region of the lower work-coil (Fig. 2) and increased in brightness. It was found possible to switch off the higher frequency output and maintain the plasma on the lower frequency alone (Fig. 3), but the power and diameter of the plasma then decreased. Attempts to initiate a plasma at 280 kc/s,

using both the graphite rod and Tesla discharge techniques, were unsuccessful.

Although no direct measurements of the power supplied to the plasma by each generator have yet been made, approximate values were obtained by a load substitution method: the power dissipated in a dummy load, a graphite cylinder of the dimensions required to produce the same load conditions as the plasma itself, was determined by measuring the equilibrium temperature of the graphite load in a slow stream of nitrogen and assuming that the power supplied was equal to the rate of loss of heat by radiation (convection losses are comparatively small). This method has been shown by Reed[9] to give results which agree well with those obtained by using the conventional water-cooled calorimeter. The output from generator No. 2 was about 13 kW with generator No. 1 on (Fig. 2) and 10 kW with generator No. 1 switched off. Similar measurements on generator No. 1 indicated an output power of approximately 7 kW.

There appears to be no reason why still lower frequencies should not be used provided that: (*a*) suitable means of initiation are incorporated, either by the use of a high-frequency pilot plasma as in the present work or possibly by pressure reduction as apparently used by Dymshits; (*b*) the size of the plasma torch is increased.

RADIOBIOLOGY

Measurement of Polonium-210 in Human Blood

POLONIUM-210 is a naturally occurring alpha-emitting isotope of the uranium series derived from decay of its long-lived parent, lead-210. Polonium-210 is present in most plants and foodstuffs, as well as in human tissues[1–3]. Body burdens of this isotope are usually determined by measuring its activity in tissue samples or urine[2,4,5]. Tissue samples other than teeth are not readily available during life, however, and 24 h urine collections may be difficult to obtain and process, yet are often necessary to quantify urinary excretion. We have found that polonium-210 can be easily detected in 10 ml. human blood samples by a simple radiochemical and counting technique. The measurement of polonium-210 concentration in blood may thus be a practical method of estimating body burdens of this isotope, as well as of its parent lead-210[2]. As tobacco smoke has been shown to contain trace amounts of polonium-210[6], we have related blood concentrations to smoking habits in a group of middle-aged men.

Ten ml. samples of fresh clotted blood were weighed and digested in 30 ml. of hot concentrated hydrochloric acid, placed in plating cells with 0·5 N hydrochloric acid and 50 mg ascorbic acid, and the polonium plated on to silver planchets[4,7]. The planchets were counted for 48–72 h in low background gas-flow proportional counters[7]. Polonium-210 concentrations as low as 0·3 pc./kg blood could be reliably measured by this method. Blood samples were obtained from 100 healthy men between the ages of 45 and 54 years, all of whom resided in one suburb of Boston. Detailed smoking histories were obtained from these men, and they were divided into four groups: current cigarette smokers, current pipe and/or cigar smokers only, past cigarette smokers (had been regular smokers until a year or more previously), and individuals who had never smoked.

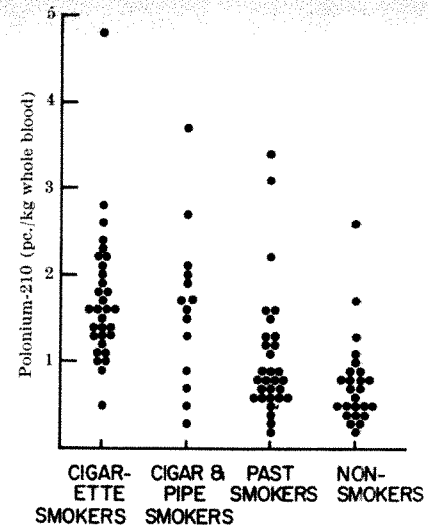

Fig. 1. Polonium-210 concentrations measured in 10 ml. blood samples from 100 healthy men 45–54 years of age

The results are presented in Fig. 1. The average polonium-210 concentration in smokers was 1·72 pc./kg blood, compared with 0·76 pc./kg in non-smokers. Although a significant difference existed between blood concentrations in cigarette smokers and non-smokers ($P < 0{\cdot}001$), a two to three-fold variation among individuals was present in each group. Such variation has also been observed among polonium-210 concentrations in pulmonary tissues of different individuals[7]. In addition, we have examined other body tissues including liver, spleen, kidney, urinary bladder and bone obtained at autopsy from ten cigarette smokers and four non-smokers. Average concentrations were very similar to those recently reported by Hill[1], but up to a three-fold variation in concentrations in each organ was observed among individuals.

The variation in blood concentrations may in part result from dietary factors. As Hill has pointed out, polonium-210 concentrations differ widely in various foodstuffs; beef and lamb kidney and certain shell fish, for example, may contain relatively large amounts of the isotope[1]. In a preliminary study of possible dietary effects, several blood samples were drawn from an 85 kg subject before and after a meal containing about 100 pc. of polonium-210 (200 g of beef kidney). Blood polonium-210 concentrations were 0·98 pc./kg before the meal and rose to a maximum of 1·56 pc./kg 12 h after the meal, which suggests that a significant fraction of the isotope present in food is absorbed into the blood.

In separate experiments in four heavy cigarette smokers, blood samples were obtained before and at regular intervals after sudden complete cessation of smoking. Blood polonium-210 concentrations fell an average of 27 per cent during the first week after smoking was stopped, but thereafter changed very little during the next 4–8 weeks.

In addition to the polonium-210 normally inhaled and ingested by the general population, it has been estimated that cigarette smokers retain an excess of about 1·5 pc./day per twenty cigarettes, much of which may be cleared from the lungs in the mucous sheet and swallowed[6,7]. The present results indicate that such small differences in chronic environmental exposure to polonium-210 can be detected in 10-ml. blood samples from exposed individuals. The values reported here should serve as a baseline to evaluate concentrations found in blood of individuals possibly exposed to high environmental levels of polonium-210 or its parent isotopes. In preliminary experiments, detectable concentrations of radium were found in 10-ml. blood samples from two normal individuals. Analysis of small blood samples, therefore, may also prove useful in estimating body burdens of alpha-emitting isotopes other than polonium-210.

We thank Dr. Edward P. Radford, jun., of the University of Cincinnati College of Medicine for confirming our counts on several of these samples in his laboratory. Caesium-137 in Edible Freshwater Fish

KNOWLEDGE of radioactivity in fish is largely limited to determinations made of the strontium-90 occurring in certain ocean species and to some attempts at the evaluation of caesium-137 content (^{137}Cs) of the same or similar specimens. Häsanen and Miettinen[1] found concentrations of the order of nanocuries of caesium-137 per kilogram (nc./kg) in freshwater fish. These were taken from lakes in Finland during 1962 and 1963 in the course of an investigation into sources of caesium-137 other than caribou and reindeer meat in the Laplander's diet. This finding could have been predicted from the earlier work of Pendleton and Hanson[2], which demonstrated the rapid accumulation of caesium-137 by various aquatic forms through several trophic levels in a freshwater pond contaminated with caesium-137. Caesium-137 in these organisms was found to reach concentrations several orders of magnitude greater than those found in the surrounding water.

During the first 3 months of 1965, the concentrations of caesium-137 present in freshwater fish available commercially in the Chicago area were similar to those found earlier in Finland (Table 1). The fish (which were purchased at random in local food markets) were boned fillets (except for smelts) and ready to cook. Both the concentration of caesium-137 and of potassium-40 were determined by gamma-ray spectrometry in 1–2-kg samples of fresh fish using conventional low-background techniques. A number of varieties of ocean fish were also examined and showed appreciably lower concentrations of caesium-137 but similar potassium levels (Table 1). This inherent difference between salt and freshwater species as regards the content of caesium-137 had been previously noted by Häsänen and Miettinen[1].

The caesium-137 concentration present in fish depends primarily on three factors: (1) the concentration of the radionuclide in the water environment; (2) the accompanying level of potassium (ratio of caesium-137: potassium); (3) the position of the fish in question in the aquatic food chain (that is, the trophic level). Published values of caesium-137 in salt and freshwater are sparse. However, monthly measurements in Lake Huron showed average concentrations of 0·4 and 0·3 pc./l. during 1963 and 1964, respectively[3]. During this same interval the concentration in lakes and rivers in the vicinity of Chalk River, Ontario (presumably uncontaminated by reactor wastes), was three to four times greater than that in Lake Huron[3]. Surface waters of the Pacific Ocean sampled in mid-1953 indicated an average level of 0·6 pc. caesium-137/l. (ref. 4). Profiles of caesium-137 activity in ocean water have shown decreasing concentration with depth[5]. Judging by the limited data available, there did not appear to be appreciable differences between the concentration of caesium-137 in salt and freshwater. However, the possibility exists that closed lakes which do not possess large dilution capacity may contain higher levels of caesium-137 because they collect the run-off from large areas. Conversely, because of the large dilution effect possible in the oceans, the effective concentrations may be much lower than that observed in surface waters.

The potassium content of the oceans is ten to several hundred times greater than of freshwater. The value in the oceans, based on a large number of analyses, is fairly constant, and is given as 380 parts per million (p.p.m.)[6]. The few measurements taken in the Great Lakes show values of a few p.p.m., with smaller lakes and rivers in the area containing somewhat higher amounts[7]. Amounts in closed lakes in this region and further north are an order of magnitude higher, with values approaching marine concentration in some instances[7]. The concentrations of rubidium and stable caesium are several orders lower than that of potassium in both salt and freshwater and are almost insignificant[6,7].

The greater concentration of caesium-137 in freshwater fish, seen in Table 1, probably reflects, in the first place, the higher caesium-137 : potassium ratio present in freshwater[8]. The trophic level is also a factor—as shown by the higher caesium-137 concentration in carnivorous fish as opposed to plankton feeders and other non-carnivorous fish, in both salt and freshwater. The lower concentrations in lake perch and smelt may also result from younger age at capture as well as different feeding habits.

The question now arises as to what effect the presence of relatively high concentrations of caesium-137 in freshwater fish may have on the average intake by human beings

* The common or commercial names of fish are used here instead of taxonomic names because of the difficulty in determining the latter with any precision with frozen, dressed fish.
† 'Carnivorous' is meant to imply feeding on fish and other animals smaller than the fish in question.

in their diet and on the resulting body burden. Measurements of caesium-137 in the diets of inhabitants of the Chicago region have been made as part of the "Tri-City Food Sampling Program"[9]. During 1964 the average adult intake of caesium-137 was found to be 200 pc./day or 45 pc./g potassium. Whole body measurements of human subjects in the Chicago area showed a relatively constant average level of 150 pc. caesium-137/g potassium during the latter half of 1964 (ref. 10). This concentration of caesium-137 in man was taken to be the equilibrium level attributed to an intake of 200 pc./day for several months. The composite diet in question contained 8 kg of fish and 73 kg of meat per annum. The fish actually sampled in the study were primarily saltwater varieties, and accordingly the daily intake of caesium-137 from fish was ~5 pc. If we consider that equal amounts of salt and freshwater fish are consumed each day, and take average values from Table 1, the daily intake of caesium-137 from fish becomes 15 pc. Restricting the fish consumption to freshwater varieties results in an average intake of 30 pc. caesium-137/day from fish. This will, at most, produce a 15 per cent increase in the average daily intake of this radionuclide. Those persons who consume larger quantities of fish than implied by the standard diet, or who substitute fish for meat, will have a correspondingly higher daily intake of caesium-137. An extreme, though still feasible, example would be one in which an individual, on an otherwise normal diet, ate a pound of carnivorous freshwater fish per day and little or no meat. This would lead to an intake of 1,200 pc./day and an equilibrium body burden of 900 pc./g potassium (according to the relationship that 200 pc./day intake will lead to an equilibrium burden of 150 pc./g potassium). For a 70 kg man (standard man), containing 140 g of potassium, the whole-body burden of caesium-137 would be 0·13 μc. The body burden of caesium-137 in Eskimo and Laplander populations, depending wholly or in part on caribou and reindeer as a source of fresh meat, ranged from a few tenths of a μc. to as high as 3·0 μc. during 1964 (refs. 11–13). Thus it would appear that individuals living in the United States and Canada (and probably in the mid-latitude regions of Europe and Asia also), who regularly consume as much as a pound of carnivorous freshwater fish in a day, could approach the caesium-137 body burden of Arctic and sub-Arctic peoples who depend on caribou or reindeer as a prime source of meat.

We thank Dr. R. W. Wolfgang of this Division for advice concerning the feeding and other habits of the fish involved in this study. This work was supported by the U.S. Atomic Energy Commission.

A Liquid Scintillation Method for measuring Carbon-14 Uptake in Photosynthesis

THE accurate determination of the radioactivity of stock sodium carbonate solutions and the correction of the radioactivity of membrane filtered algae to zero thickness are two of the greatest barriers to accurate productivity measurements using carbon-14.

The purpose of this paper is to outline a method which has been very useful in a recently completed photosynthesis study, and which may offer a solution to these problems.

Goldman[1,2] has dealt successfully with these two problems by oxidizing all organic carbon to carbon dioxide, and measuring carbon-14 activity in the gas phase. This method is relatively time consuming, and it does not adapt itself readily to the rapid counting of large numbers of planchets.

Jitts and Scott[3] have used liquid scintillators to estimate zero thickness corrections by counting labelled plastic films on a Geiger–Müller counter, then dissolving the films in liquid scintillator solution to determine the activity accurately. In their calculations it is assumed that the quenching properties of plastic film are similar to those of the equivalent weight of algae.

The advantages of the method described here are: (1) All photosynthesis determinations may be corrected individually for self-absorption and counting efficiency. (2) The high efficiency of liquid scintillation counting makes more rapid and more accurate counts possible. (3) The method is adaptable to field use, and saves considerable time in handling papers and planchets. (4) The activity of stock solutions can be determined accurately and directly, using the same method.

The scintillator solution is made up as follows: 100 g naphthalene; 7 g 2,5-diphenyl oxazole (PPO); and 0·3 g dimethyl, 2,2,*p*-phenylene*bis* (5 phenyloxazole) (dimethyl-POPOP) are dissolved in 1 l. of reagent-grade dioxane. The scintillator solution may be used for counting aqueous carbon-14 samples of all sorts; it gives good counting efficiencies even when it contains almost 30 per cent water[4].

Determination of carbon-14 uptake by algae. After termination of a photosynthesis determination the algae are filtered on to a 'Millipore' membrane in the usual manner. The membrane and its contents are transferred directly to a liquid scintillator vial containing the scintillator solution; vigorous shaking will dissolve the damp 'Millipore' quickly. Dry 'Millipore' membrane is insoluble in this scintillator solution, and so membranes must be taken directly from the filtering apparatus while they are still wet. The membranes must be completely dissolved before counting commences or the results will be highly variable. A slight greenish tinge, which may cause colour quenching, will appear in the scintillator solution just after the membrane has been dissolved if the layer of phytoplankton is particularly heavy. This colour disappears within a few hours, and counting should be delayed until it disappears.

Samples must be counted at above 5° C, since the solution freezes at 3°–4° C. After counting, an appropriate volume (10–100 lambdas) of carbon-14 labelled liquid toluene standard is added to each sample, and all vials are re-counted. The vials must be shaken immediately before counting in both cases, as the algae (or remnants thereof) settle out within a few minutes. The addition of a thixotropic gel, such as 'Cab-O-Sil *M*-5' (Godfrey L. Cabot, Inc.), should eliminate this problem with very little loss of counting efficiency, if an automatic counter is to be used, or if samples are of very low activity. The counting efficiency for each vial is $E = (C' - C)/S$, where C' is the number of counts per minute measured after addition of the toluene standard, C is the number of counts per minute of the sample alone, S is the actual radioactivity of toluene standard added in disintegrations per minute, and E is efficiency of the counting apparatus (all counts cor-

rected for background). The correction for self-absorption will vary slightly from sample to sample. C/E will give corrected figures (d.p.m.) for carbon-14 uptake.

Activity of carbon-14-labelled sodium carbonate stock solutions. A small, accurate volume of stock labelled sodium carbonate solution may be pipetted directly into a vial of the scintillator solution and counted. The vials may be standardized and corrected for efficiency in the same manner as for algal samples. Ten to twenty-five lambdas of stock solution will normally be adequate, if the stock activities are of the order of 5–10 μc./ml.

The following results represent counts on planchets selected at random from a day's photosynthesis determinations on a small turbid pond. All determinations were carried out in 250-ml. reagent bottles suspended directly in the lake from a transparent float. 0·5 ml. of labelled sodium carbonate solution of approximately 5 μc. was added to each bottle. The incubation time was 4 h, from 10 a.m. to 2 p.m. Exactly 75 ml. from each bottle were fixed with 0·5 ml. of 40 per cent formalin and filtered on to a 'Millipore' *HA* membrane, 2 in. in diameter. Membranes were first dried and counted with a 'Tracerlab' *FD*-1 gas flow Geiger–Müller tube with a 'Mono-mol' resin window and a 'Tracerlab Compumatic II' scaler; then dampened and counted as described above in a 'Tracerlab' *LSC*–10 *B* liquid scintillation counter using the same scaler.

The efficiencies of both the gas flow and liquid scintillation method were calculated from the corrected liquid scintillation counts as determined by adding carbon-14-labelled toluene standard.

The counts and comparative efficiencies of the two methods are set out in Table 1.

Table 1

Depth (m)	Gas flow Geiger–Muller (d.p.m.)	Liquid scintillator (d.p.m.)	Actual carbon uptake by algae (d.p.m.)
Surface	4,416	10,283	28,638
1	3,767	11,735	32,671
2	1,416	3,814	10,615
2	1,478	4,384	12,205
5	244	726	2,022
5	248	748	2,082
Dark bottle	232	547	1,523

	Average percentage efficiency of counting	Standard deviation
Gas flow	13·09	1·47
Liquid scintillator	35·92	0 65

The high counting efficiency and low standard deviation, coupled with the individually determined efficiencies and reduced manipulation of filter membranes, make the liquid scintillation method desirable where primary production is very low or erratic.

I thank Prof. G. W. Comita of the North Dakota State University Department of Zoology for providing space, field equipment, and financial support, and Dr. D. C. Zimmerman of the North Dakota State University Chemistry Department for the use of radiation detection facilities, as well as for several helpful discussions on liquid scintillation counting. I also thank Prof. Comita, Dr. Zimmerman, Mr. Charles Elton and Mr. Christopher Mathews for reading the manuscript. This investigation was supported by a U.S. Public Health Service Special Fellowship to me, a National Science Foundation grant to Prof. Comita, and by the North Dakota Institute for Regional Studies.

CHEMISTRY

Analysis of Volatile Substances in Samples containing Non-volatile Substances by Process Gas Chromatography

RECENTLY, we experienced difficulties with the automatic analysis by gas chromatography of a process stream consisting of a liquid mixture of organic chemicals. These arose because traces of non-volatile tars and polymers in the sample eventually accumulated in the entrance of the first column of the chromatograph. (This chromatograph normally uses two columns to perform the analysis and has a thermal conductivity detector. The first column is used to separate and backflush volatile heavy ends out of the analyser; the second column completes the separation of the substances to be analysed.) Eventually, after a series of analyses, the accumulation of non-volatile materials in the first column was sufficient to block it completely, thus putting the analyser out of commission. The analyser was, in fact, injecting 10-μl. samples every 15 min into a 0·125-in. bore column. The concentration of non-volatiles was about 0·5–1·0 per cent by weight. Blockage occurred after 7–10 days of continuous operation.

The problem described here rarely arises in gas chromatography in laboratories, as the frequency of analysis is rarely as high. Even if a column blocks up in the laboratory, it is usually an easy matter to change it. This state of affairs cannot be tolerated with a process instrument where a minimum of 6 months' continuous operation is almost mandatory. It was, in fact, essential that this problem be solved to achieve fully reliable on-line analysis. This has now been done and this communication describes the essence of the method.

I considered that it was necessary to remove the non-volatile materials from the first column by washing the column with a liquid solvent. An immediate objection to this is the damaging effect of the solvent to the column. This can be avoided by using an extra column which we call a "cleanse column" together with a column switching valve. The cleanse column is, in fact, an unpacked 0·125-in. bore tube about 1–2 ft. long and the system is operated as follows.

The sample is injected into the cleanse column. The non-volatile constituents of the sample stick to the walls of the cleanse column tube and the volatiles pass on to the analytical columns. The column switching valve is then shifted. This isolates the sample valve and cleanse column from the rest of the chromatograph. While the analysis proceeds, the cleanse column and sample valve passages are flushed out with a suitable solvent to remove the non-volatiles. Residual solvent is removed by purging the lines with pure dry instrument air.

Before a subsequent analysis is due to commence, the column switching valve is reversed, thus re-connecting the sample valve and cleanse column into the carrier gas supply. This is done during the time the first column is being backflushed, so that residual air is purged clear by the carrier gas flow and does not affect the analysis. The next analysis cycle can then be commenced.

The system uses some 40–60 ml. of solvent per analysis or 4–6 l. per day. A solvent recovery still is used in conjunction with the analyser. The solvent must, of course, readily dissolve the non-volatiles in the sample. The boiling-point of the solvent should be preferably some 20°–30° C above the analyser operating temperature. This is to prevent formation of vapour locks in the lines, thus preventing free flow of the solvent. The solvent should be sufficiently volatile, however, otherwise a prolonged air purge is required to remove remaining traces from the system before starting the next analysis. The technique described above has permitted non-interrupted operation of a process chromatograph for

almost 6 months at the time of writing, where previously the maximum period was 10 days.

To the best of my knowledge, this is the first example of the technique being used in on-line process analysis. It is understood that a similar technique has been tried in the laboratory with a process chromatograph for the removal of sugars[1] in the analysis of wines. This analyser was not, however, ever installed on a running process.

I thank those staff of Beckman Instruments, Inc., who encouraged me to try out the technique.

Microwave Spectrum of Silyl Isocyanate

THE microwave spectra of silyl isothiocyanate[1] and silyl azide[2] have shown them to be symmetric and asymmetric tops respectively. We report here that silyl isocyanate has a spectrum which, although that of a symmetric top, has numerous very unusual features.

The spectrum consists of several series of lines with first order Stark shifts separated by about 5 Gc/s. Each series extends over about 2 Gc/s and is roughly divided into groups. The lower frequency groups of each series are clear cut, but beyond about the third they become more complicated and are difficult to distinguish. The lowest frequency group of each series was assigned to the ground vibrational state and gave a good fit when frequency was plotted against K^2. In particular the lines assigned to $K = 1$ show no splitting and the lines $K = 3$ show the characteristic intensity increase of molecules with three equivalent protons, this indicating a symmetric top.

The bulk of the remaining lines were assigned to molecules in excited states of a low-frequency vibration. Those groups attributed to the first excited state each possessed an l-type doublet and a central group, indicating a degenerate vibration, associated with bending of the heavy atom chain. The intensities of the groups suggested a vibration frequency of less than about 50 cm^{-1}, and the splitting of the l-type doublets, assuming the small amplitude approximation, yielded about 30 cm^{-1}. This figure should be compared with 54 cm^{-1} in silyl isothiocyanate[1] and 220 cm^{-1} in silyl acetylene[3,4]; apparently the present low value arises from a very low restoring force in the bending rather than the atomic masses.

Spectra were obtained of the most abundant and isotopically substituted species. Molecules containing silicon-29, silicon-30 and carbon-13 were studied in natural abundance, whereas artificial substitutions of oxygen-18, nitrogen-15 and deuterium were made using the reaction of cyanic acid and trisilyl amine[5]. In all symmetric cases the simplest analysis of the data yielded very large values of the centrifugal distortion constant D_{JK} (500–670 kc/s), while D_J was "normal" (about 1 kc/s). With more detailed treatment significant higher order constants were found in some cases. The partially deuterated, slightly asymmetric, molecules gave a straight line through the points $K = 0$, 2, 3 and the mean of $K = 1$ when frequency was plotted against K^2; the slope gave a value for D_{JK}. The points $K = 4$ and 5 were well off (14–90 Mc/s) the lines. All calculated constants are in Table 1.

An attempt was made to determine the "r_s" structure; this method attempts, with much success for "regular" molecules, to approximate the equilibrium structure to within a few thousandths of an Ångstrom unit[6]. All atoms except nitrogen were placed using Kraitchman's equations[7]; because nitrogen is near the centre of mass its true "r_s" position was difficult to determine. It was placed using, besides a simple first-moment method, a double first-moment procedure in which the shift in centre of mass on full deuteration was observed from the change in "r_s" positions of silicon. From this two simultaneous centre of mass equations were set up having as unknowns the nitrogen position and the height of the silyl pyramid. These first moment values agreed and were used in the derived structure. Table 2 contains this as well as those of related molecules. It is seen that the present N—C distance is much shorter than that of the other molecules, suggesting that the nitrogen and/or carbon positions may be incorrectly determined. While this is entirely possible, it is noteworthy that the present C—O distance is comparable with that of related molecules and that the S—O distance is 0·068 Å shorter than the sum of the Si–N distance in silyl isothiocyanate and the N–O distance in cyanic acid. Furthermore, the derived H–Si and D–Si parameters show no self-consistency and are very different from those of other silyl compounds.

Table 1. ROTATIONAL AND CENTRIFUGAL DISTORTION CONSTANTS OF SILYL ISOCYANATE

Species	Rotational constant(s) $B_0(C_0)$ (Mc/s)	D_J (kc/s)j	D_{JK} (kc/s)	Others (kc/s)

$^{28}SiHD_2{}^{14}N^{13}C^{16}O$	2,400 86 2,376·12		578	

Table 2. STRUCTURE OF SILYL ISOCYANATE AND RELATED MOLECULES

Molecule	Ref.	r(O–C) (Å)	r(C–N) (Å)	r(N–Si) (Å)	r(H–Si) (Å)	∠(H–Si–H)
SiH_3NCO	Present	1 179	1 150	1·699	1·506	110° 24′
SiD_3NCO	Present				1 514	112° 12′
SiH_3NCS	1		1·211	1·714	1·488	111° 22′
SiH_3Cl	8				1·483	110° 58′
SiD_3Cl	8				1·480	110° 52′
SiH_3CCH	9				1·488	110° 12′
HNCO	10	1 171	1·207			
CH_3NCO	11	1·18	1 19			
$(SiH_3)_3N$	12			1 74	1·54	

Thus silyl isocyanate, though a symmetric top, is an unusual one, in comparison with both chemically related molecules and other symmetric tops. Other isocyanates (cyanic acid, methyl isocyanate, germyl isocyanate[13]) and isoelectronic silyl azide all have bent heavy atom configurations. Nevertheless, the low frequency band, with its correspondingly low force constant, reflected in the very high values of D_{JK} (ref. 14), suggests that the force constraining silyl isocyanate to the symmetric configuration is rather weak. The vibration is probably of large amplitude, with considerable anharmonicity, which makes use of the small amplitude approximation dubious, particularly in treating l-type doublets and deriving structural parameters[15]. The latter is especially evident here. The K-irregularities of the partially deuterated species probably arise because the energies of the rotational levels involved are becoming comparable with those of levels in the first excited vibrational state, with possibilities of Fermi resonance.

From first order Stark splittings of the lines $K = 2$ and 3 of the transition $J = 4 \rightarrow 5$ a value of 2·15 ± 0·10 D was obtained for the dipole moment.

New Metal-rich Phosphides of Niobium, Tantalum and Tungsten

PREVIOUS investigations[1–5] of the niobium–phosphorus and tantalum–phosphorus systems indicate that only two intermediate phases occur in each system, a monophosphide (which shows a varying amount of stacking disorder in the structure) and a diphosphide. These results are based on investigations of the products formed when the metals react with phosphorus at temperatures below 1,100° C. In the tungsten–phosphorus system, the occurrence of tungsten monophosphide and a high and a low temperature form of tungsten diphosphide has been observed[6–8]. No further intermediate phases appear to be formed by direct reaction between tungsten and phosphorus below 1,100° C. It has been reported, however, that tungsten phosphides containing less than 50 atom per cent phosphorus can be prepared by fused salt electrolysis. Thus, Hsu *et al.*[10] obtained a crystalline compound of composition W_3P by electrolysis of a fused sodium metaphosphate bath containing tungsten trioxide and sodium chloride at temperatures below 900° C. This compound was described as having the body-centred tetragonal iron triphosphide-type structure with cell dimensions $a = 9{\cdot}890$ Å; $c = 4{\cdot}808$ Å.

I have started a re-investigation of these systems and have extended the studies to include temperatures much higher than those previously covered. Some preliminary results are quoted here.

In the first stages of the re-investigation, phosphide samples were prepared by heating mixtures of red phosphorus and the appropriate metals in evacuated and sealed silica tubes. X-ray powder analyses of these products are in general agreement with the earlier work, while some new features were observed relating to the stacking-disorder phenomena in the niobium monophosphide and tantalum monophosphide structures[5]. These new observations will be discussed in a forthcoming paper to be published elsewhere. In agreement with Hulliger's recent report[9], niobium diphosphide and tantalum diphosphide crystallize with the niobium diarsenide-type structure. Tungsten diphosphide, originally reported to crystallize with molybdenum diphosphide-type structure[7], has recently been obtained with the niobium diarsenide-type structure[9]. In the present investigation the occurrence of both forms of tungsten diphosphide was confirmed; the molybdenum diphosphide-type phase forms when the reaction temperature exceeds about 700° C, while the niobium diarsenide-type occurs at lower temperatures. Heat-treatment of the high-temperature form at 600° C for two days did not yield any detectable amounts of the low-temperature form, which shows that the transformation is very sluggish. The two phases have the same ideal crystallographic formula, but small deviations from the ideal composition for one or both cannot be excluded.

In preliminary attempts to explore the systems at temperatures above 1,100° C, phosphide samples initially prepared in silica tubes were heated in an argon-arc furnace. The phosphorus losses on rapid heating were found to be surprisingly small for samples containing less than 50 atom per cent phosphorus, and X-ray examination of the products indicated that several new intermediate phases had been formed.

Rapidly arc-melted tungsten–phosphorus samples invariably consisted of three phases: α-tungsten, tungsten monophosphide and a further phase. The diffraction lines from this phase can be indexed on the basis of a body-centred tetragonal unit cell having dimensions $a = 9{\cdot}858$ Å; $c = 4{\cdot}800$ Å. Comparison with the diffraction pattern of Mo_3P (α-Zr_3S-type structure[11]) indicates a very close structural resemblance, and it seems highly probable that the two compounds are isostructural. The composition W_3P is therefore assigned to the new tungsten phosphide. It appears likely that this phase is identical with the W_3P phase obtained by Hsu *et al.* The unit cell dimensions agree fairly well and in the absence of single-crystal data it is very difficult to make an unambiguous distinction between the Fe_3P- and the α-V_3S-type structures, as explained in refs. 7 and 11.

The powder patterns of the arc-melted niobium–phosphorus and tantalum–phosphorus alloys showed greater complexity than those of the tungsten–phosphorus alloys. At about 25 atom per cent phosphorus, phases crystallize with the Ti_3P-type structure and accordingly seem to be Nb_3P and Ta_3P. These compounds are probably the most metal-rich in their respective systems. More phosphorus-rich preparations yielded very line-rich diffraction patterns (particularly in the case of the niobium phosphides) which could not be easily interpreted. However, well-developed single crystals were often formed in the alloys, and extensive X-ray investigations using single-crystal techniques have therefore been started. So far, a tantalum phosphide with the composition Ta_5P_4 has been characterized crystallographically by a combination of single-crystal and powder methods. The unit cell is orthorhombic and contains four formula units. The space group is most probably $P\,n\,n\,m$ and the intensity data indicate strongly that all atoms occupy $4g$ positions in this space group.

Since the technique of arc-melting produces alloys which are frequently grossly inhomogeneous, a phase-analysis of arc-melted alloys cannot be expected to furnish reliable information about the phase-relationships at high temperatures. A series of high-temperature annealing treatments under well-defined conditions has therefore been started. Detailed reports of the phase-analytical as well as the X-ray crystallographic data obtained will be published elsewhere. The crystallographic data obtained in the present preliminary investigation are collected in Table 1.

In view of the present results it might be asked whether the new phases obtained by arc-melting are in fact thermodynamically unstable at lower temperatures or whether other factors, such as activation energy barriers, prevent their formation below 1,100° C. A conclusive answer to this question cannot be reached in the absence of quantitative thermodynamic information. However, there are strong reasons to believe that W_3P is truly unstable at lower temperature. While this phase can

Table 1. CRYSTALLOGRAPHIC DATA ON NIOBIUM, TANTALUM AND TUNGSTEN PHOSPHIDES

Phosphide	Structure type	a (Å)	b (Å)	c (Å)	$\beta°$
Nb_3P	Ti_3P	10·128		5 091	
NbP	NbAs	3·334		11·377	
NbP_2	$NbAs_2$	8·8715	3·2663	7 5194	119·097°
Ta_3P	Ti_3P	10 154		5 012	
Ta_4P_4	(orthorhombic)	14 420	11·547	3·400	
TaP	NbAs	3·319		11 341	
TaP_2	$NbAs_2$	8·8608	3 2677	7 4882	119·308°
W_3P	α-V_2S (?)	9 858		4·800	
WP	MnP	5 732	3 249	6 222	
α-WP_2	$NbAs_2$	8 5022	3·1695	7 4660	119 367°
β-WP_2	MoP_2	3·166	11 161	4·973	

The unit cell dimensions were determined in Guinier-Hägg type focusing cameras using copper $K\alpha_1$ radiation with silicon ($a = 5{\cdot}4305$ Å) as the internal calibration standard.

For NbP_2, TaP_2 and α-WP_2 a least-squares refinement of the powder diffraction data indicated standard deviations for a and c of 0 0007 Å, for b 0 0002 Å and for β 0 005°. The relative accuracy of the unit cell dimensions for the remaining phases is estimated to be higher than 0 03 per cent.

obviously be retained from the high-temperature range owing to the rapid cooling process in the arc furnace, it disappears completely from W_3P-containing samples on annealing at temperatures between 800° and 1,000° C, and the only remaining phases are tungsten and tungsten monophosphide. Hsu *et al.* reported that their W_3P phase was unstable above 900° C. This suggests that the energetic conditions prevailing during electrolysis permit the formation of metastable W_3P, which can then be recovered only at moderately high temperatures without extensive decomposition.

The Nb_3P and Ta_3P phases remain unchanged after prolonged heat-treatment at 1,000° C, and it therefore appears likely that their formation at low temperatures is prevented by reaction kinetic factors only.

This investigation is supported by grants from the Swedish Natural Science Research Council.

Photochemistry of the *S*-Nitroso Derivatives of Hexane-1-thiol and Hexane-1,6-dithiol

S-NITROSOHEXANE-1-THIOL, $CH_3(CH_2)_5SNO$, and di-(*S*-nitroso-)hexane-1,6-dithiol, $ONS(CH_2)_6SNO$, were prepared by the method reported by Saville[1]. Their electronic spectra in hexane solution were measured and were found to be similar to the spectrum of *S*-nitrosotoluene-α-thiol[2]. The relevant data are presented in Table 1.

Table 1. ELECTRONIC SPECTRA OF THE *S*-NITROSO DERIVATIVES OF THIOLS

Thiol	λ_{max} (Å)	ε_{max} (M^{-1} cm^{-1})	λ_{max} (Å)	ε_{max} (M^{-1} cm^{-1})
Toluene-α-thiol	5600	26	3400	1030
Hexane-1-thiol	5500	21	3400	940
Hexane-1,6-dithiol	5500	42	3400	1830
Assignment to transitions.	$n \longrightarrow \pi^*$		$n_0 \longrightarrow \pi^*$	

As can be seen from the data in Table 1, the ε values for the di- and mono-*S*-nitrosated hexane thiols bear a ratio to each other of very nearly two as would be expected from their structures.

Irradiation at 3650 Å of the mono compound in methanol solution causes photolysis according to the stoichiometry:

$$2RSNO \xrightarrow{h\nu} RSSR + 2NO \quad (R = \text{hexane})$$

The reaction mechanism is similar to that reported for the photolysis of *S*-nitrosotoluene-α-thiol[2].

Irradiation of the di-nitrosated compound at 3650 Å caused photolysis, and the products were a wax-like solid and nitric oxide. The solid product had a melting point of 35° C and a molecular weight (Rast's method) of 285. Elemental analysis was consistent with the empirical formula $(CH_2)_6S_2$. From these data it would appear that the solid product was largely 1,2,9,10, tetrathia*cyclo*-hexadecane.

The mechanism of the photolysis probably includes the following steps:

$$ONS(CH_2)_6SNO \xrightarrow{h\nu} ONS(CH_2)_6S\cdot + NO$$

$$ONS(CH_2)_6S\cdot + ONS(CH_2)_6SNO \rightarrow ONS(CH_2)_6S_2(CH_2)_6SNO + NO$$

$$2ONS(CH_2)_6S\cdot \rightarrow S(CH_2)_6S_2(CH_2)_6S$$

$$ONS(CH_2)_6S_2(CH_2)_6SNO \xrightarrow{h\nu} ONS(CH_2)_6S_2(CH_2)_6S\cdot + NO$$

$$ONS(CH_2)_6S_2(CH_2)_6S\cdot \rightarrow S(CH_2)_6S_2(CH_2)_6S + NO$$

Work is proceeding on this and similar systems in order to elucidate a general mechanism for the photolysis of compounds containing two SNO groups.

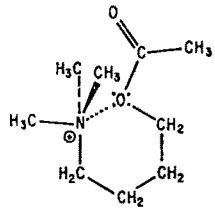
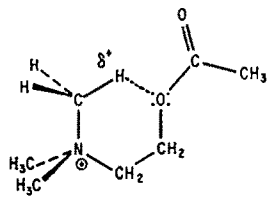
Effects of Solvents on Acetylcholine Conformation



IN earlier communications[1-3] we reported the results of our investigations with acetylcholine and related substances. These led us to conclude that the acetyl group is activated primarily by an inductive influence of the quaternary nitrogen. This conclusion was based in large measure on the carbonyl stretching frequencies which were observed for acetylcholine and its homologues in ethanol, as well as on their rates of hydroxylaminolysis in water.

In a recent communication, Canepa and Mooney[4] challenged these data and conclusions. They reported the carbonyl stretching frequencies for acetylcholine in water and ethanol and called attention to the well-known influence of the solvent on the carbonyl stretching frequency. They suggested that the solvent hydrogen-bonding to the carbonyl group could explain the observed difference in the energies of absorption between acetylcholine and ethylacetate and, more particularly, they dismissed the possibility of an inductive onium effect. In a subsequent paper Canepa[5] proposed that the conformation of acetylcholine in the crystal and in water involved an interaction between the quaternary nitrogen and the unshared electrons on the ester oxygen. Although no data are offered which support his conclusions for the behaviour of acetylcholine in aqueous solution, he insisted that the bond angles encountered in the crystal allow an interaction between the positive-charged onium nitrogen and the ester oxygen.



We have undertaken to examine some of the points raised by these publications and wish to report the results of our investigations of acetylcholine and related homo-

logues and derivatives in a number of solvents which support our conclusions of an inductive influence by the quaternary nitrogen on the carbonyl stretching frequency and which can account for the "active" acyl character of acetylcholine.

The sources, or the synthesis, of all the compounds examined have been reported in our previous publications[1,2] with the exception of *N*-acetoxytrimethylammonium bromide. This substance was prepared by the method of Geiger[6]. The determinations of the infra-red spectra were carried out using a Perkin–Elmer '221-*G*' spectrophotometer programmed for maximum resolution. Attenuated total reflectance (ATR) spectra were determined using a Perkin–Elmer ATR accessory with a KRS-crystal. Nuclear magnetic resonance studies were carried out with a 'Varian' spectrometer at 60 Mc/s in deuterium oxide.

Table 1. INFRA-RED SPECTRA BY TRANSMISSION

	DMSO ($\nu_{C=O}$)	Ethanol ($\nu_{C=O}$)

$CH_3-N^{\oplus}(CH_3)_2-CH_2-O-C(=O)-CH_3, Cl^{\ominus}$	1772	1780
$CH_3-N^{\oplus}(CH_3)_2-CH_2-CH_2-O-C(=O)-CH_3, Cl^{\ominus}$	1744	1760
$CH_3-N^{\oplus}(CH_3)_2-CH_2-CH_2-CH_2-O-C(=O)-CH_3, I^{\ominus}$	1737	1752, 1732
$CH_3-N^{\oplus}(CH_3)_2-CH_2-CH_2-CH_2-CH_2-O-C(=O)-CH_3, I^{\ominus}$	1734	1748, 1728
$N(CH_3)_2-CH_2-CH_2-O-C(=O)-CH_3$	1733	1748, 1728
$CH_3-CH_2-O-C(=O)-CH_3$	1733	1748, 1728

The data given in Table 1 report the carbonyl stretching frequencies in dimethylsulphoxide for a number of esters related to acetylcholine. These results show quite clearly that, in a solvent with which no hydrogen bonding can take place, there exists a relationship between the stretching frequency for the carbonyl group and the position of quaternary ammonium group.

This conclusion is supported by results from experiments in which deuterium-labelled dimethylsulphoxide was used as a solvent. No shift was observed in the carbonyl absorption spectra of acetylcholine and its homologues, indicating no solvent proton interaction with this functional group of the molecule.

The closer the onium group is to the carbonyl group, the higher is the observed energy. More particularly there is an evident impact of the quaternary nitrogen in acetylcholine when one compares its carbonyl spectrum with that of dimethylaminoethylacetate.

Furthermore, this result firmly argues against an interaction between the quaternary nitrogen and the ester oxygen in that one would expect a greater effect on the carbonyl stretching frequency of 3-dimethylaminopropylacetate methiodide and even 4-dimethylaminobutyl acetate methiodide since the bond angles would allow an even closer approach than in acetylcholine (see Figs. 1 and 2).

The values for the $\nu_{C=O}$ of acetylcholine, dimethylaminoethylacetate, and ethylacetate in DMSO, and DMSO–water, ethanol, and ethanol–water are recorded in Table 2. It is evident from these data that, while a solvent effect may be readily observed, the $\nu_{C=O}$ for acetylcholine is clearly greater than the related dimethylaminoethylacetate. For example, in 50 per cent DMSO the $\nu_{C=O}$ for acetylcholine is 1,733 cm^{-1} and only 1,723 cm^{-1} for dimethylaminoethylacetate.

A more dramatic demonstration of the impact of the onium nitrogen on the carbonyl stretching frequency is shown in Table 3. The addition of hydrochloric acid to dimethylaminoacetate to neutralize the solution shifts the $\nu_{C=O}$ toward that of acetylcholine; making the solution somewhat acid increased this effect. Surely it is reasonable to assume that the proton reacts with the unpaired electrons on the nitrogen (it being the stronger base). The resultant onium character of the nitrogen behaves like the quaternary nitrogen in acetylcholine and influences the carbonyl stretching frequency in a like manner.

Table 3. EFFECT OF *p*H ON $\nu_{C=O}$

$CH_3-N(CH_3)_2-CH_2-CH_2-O-C(=O)-CH_3$	In 50% Ethanol	1723 cm^{-1}
	pH 7 - neutralized with HCl	1731 "
	At pH 2 with HCl	1735 "

There remains the remote possibility of a conformational interaction between the unshared electron pair on the ester oxygen and a proton from one of the methyl groups on the quaternary nitrogen (Fig. 3). The inductive influence of the onium nitrogen is marked and is evidenced by the shift in the infra-red C–H stretching frequency to 3,008–3,010 cm^{-1}.

An attempt was made to evaluate the contribution of this species to the conformation of acetylcholine in solution by examining the nuclear magnetic resonance spectra of this substance and related compounds. In short, no evidence for such interaction was observed. The methyl protons on the onium nitrogen exhibit a sharp absorption band at 6·8 τ like choline chloride and tetramethylammonium iodide. (We thank Dr. L. Dolby and C. Wilkins for carrying out these observations.)

Other evidence, which challenges the hypotheses of interaction between the unshared pairs of electrons on the

ester oxygen and the onium nitrogen, emerges from reactions involving carbonium ion intermediates β to a hydroxy group. These carbonium ions show no stabilization from a neighbouring hydroxyl group and these experiments argue against interaction of the type proposed[7].

Finally, in investigations of a cyclic conformation for choline sulphate, nuclear magnetic resonance studies revealed no methyl absorption splitting. This would have been expected from the restricted rotation of two of three methyl groups on the onium nitrogen. The single absorption for the methyl group in deuterium oxide and 90 per cent CD_3OD, 10 per cent deuterium oxide ruled out electrostatic interaction between the sulphate and the quaternary nitrogen. The fact that this more highly favoured six-membered ring conformation does not exist in solution emphasizes the unlikelihood of any interaction between the quaternary nitrogen and the ester oxygen[8].

BIOCHEMISTRY

Solubility-composition Relations of Gluten Proteins

IT is thought that the tertiary structure of a globular protein in aqueous solution is quite largely conditioned by the interactions between the amino-acid residues and water. In general, the expected result is a folding of the polypeptide chain(s) such that the charged residues are at the surface of the molecule while the uncharged residues are packed in the central regions of the molecule. The structure is stabilized by hydrophobic interactions and intra-chain hydrogen bonding in the interior, and at the surface by hydrogen bonding with water[1]. The ability of this theory to account for the behaviour of some globular proteins has led to attempts to derive relationships between composition and structure that may have predictive value. Two examples are Fisher's "law"[2] and Hatch's[3] polar ratio. In 1908, proteins were classified by British and American committees according to their solubility[4]; there may therefore be a relation between this classification and the predictions obtained by applying the suggestions of Fisher and Hatch. Glutenin and gliadin, the exemplars of two of the nine solubility classes of simple proteins, were used in an attempt to predict their properties in solution from their amino-acid composition.

Fisher's limiting law has the basic proposition that polar residues have a very limited solubility in the interior of a soluble protein molecule and that non-polar residues have a very limited solubility in the outer shell of the molecule. For spherical molecules with a polar outer layer of constant thickness (4 Å), the volume of polar residues in the surface will be proportional to the square of the diameter, while that of the non-polar core will increase as the cube. Thus the ratio p between the volume of the external (polar) shell and the internal (non-polar) core will fall sharply with increased diameter. The ratio p has been calculated for some thirty proteins by Fisher and he has shown that the p values are usually greater than the limiting value p_s for a sphere of appropriate dimensions. In those instances in which p is appreciably less than p_s the proteins are known to polymerize readily, presumably as a result of hydrophobic interaction between exposed non-polar portions of their cores.

Fisher's method of calculation applied to the amino-acid compositions reported by Wu and Dimler[5] for gliadin and glutenin gives values for p of 0·195 and 0·25. Corresponding p_s values are given by ideal spherical proteins of molecular weight 2·05 million and 1·1 million. It would therefore be predicted that gliadin would only be stable in solution as a spherical molecule with a molecular weight of at least two million while glutenin could exist in solution as stable spherical molecules of half this weight. In fact, the molecular weight of gliadin is in the range of 40–50,000 (ref. 6) and it behaves in solution as a reversibly associating system[7]; glutenin appears to be heterogeneous with a particle size of 1–4 million. Viscosity data[8] indicate that at low ionic strengths it is stable in an expanded form which would require $p \gg p_s$ (p_s for $1 \times 10^6 = 0{\cdot}025$; for $4 \times 10^6 = 0{\cdot}15$).

Table 1. HATCH POLAR–APOLAR RATIO

Haemoglobin (human)	1·03 (extreme)
Lactic dehydrogenase	1·16
Structural protein (mitochondria)	1·18
Gliadin	1·21
Median of forty-eight proteins	1·45
Glutenin	1 47
Cytochrome *c* (horse)	2·09
Tropomyosin	2 99 (extreme)
Ratio if glutamine and asparagine residues are apolar	
Gliadin	0·17
Glutenin	0·33
Ratio if glutamine and asparagine residues are ambivalent	
Gliadin	0 33
Glutenin	0·61

Recently, Hatch[3] has calculated a polar : non-polar ratio for forty-eight proteins with "no obvious peculiarities of amino-acid composition, such as occur in collagen, for example". Whereas Fisher (following Nemethy and Scheraga[9]) regards glutamine residues as non-polar, Hatch includes them in his polar count. (If this is done in applying Fisher's law a minimum molecular weight for glutenin of 16,000 is found—which would require a remarkably high surface–volume ratio for stability at its observed molecular weight of several million.) The position of gliadin and glutenin in relation to the extremes and median of Hatch's values for forty-eight proteins is shown in Table 1. It will be seen that Hatch's ratio would not indicate any unusual properties of gliadin and glutenin either in solubility or other properties listed in his paper. Nevertheless, the proteins are unusual enough in their solubility properties to have been regarded as types of solubility classes. It is true that their compositions have "obvious peculiarities" (one-third glutamine, one-sixth proline) and perhaps this is one reason for the relative failure of Hatch's ratio as compared with Fisher's law in predicting their properties. If Nemethy and Scheraga[9] are followed in considering glutamine and asparagine residues essentially non-polar, ratios of 0·17 and 0·33 for gliadin and glutenin are found. (If they are placed in Hatch's class of ambivalent residues together with histidine, tyrosine and tryptophan the ratios are 0·33 and 0·61.) These values seem more in accord with the general character of proteins with low Hatch ratios.

The greater success of Fisher's law, when applied to gliadin and glutenin, than of Hatch's ratio suggests that glutamine residues should not be regarded as having any polar attributes that would enforce their presence at the protein surface. The greater effort of computation necessary in applying Fisher's law appears worthwhile, although in its application it may be necessary to assume that a local preponderance of non-polar residues in a polypeptide chain may enforce their presence at the

surface, thus giving an opportunity for hydrophobic interaction in molecules that otherwise appear able to adopt a purely polar exterior conformation. Future attempts to relate protein composition with protein properties in solution should consider those classes of proteins with more extreme solubility properties and include the seed proteins and the protamines and histones.

Facilitated Diffusion in Mouse and Rat Erythrocytes

THE discussion of the effect of narcotics on the permeability of erythrocytes which appears in some text-books[1-3] is based on a report by Jacobs and Parpart[4]. These authors showed that *n*-butyl alcohol decreased the permeability of erythrocytes of certain species to glycerol and increased the permeability to glycerol in the erythrocytes of other species. In all cases reported, butanol increased the permeability to thiourea. Davson suggests in several of his writings (for example, ref. 2) that narcotics decrease the permeability "in certain special cases of erythrocyte permeability . . . [of] . . . those substances that apparently show an unusually rapid rate of penetration". Similar results were reported by Hunter *et al.*[5], and it was suggested that a carrier mechanism, or facilitated diffusion, was involved in these "special cases".

These data might suggest that glycerol crosses the membrane of some erythrocytes by facilitated diffusion and crosses others by simple diffusion but that thiourea always crosses by simple diffusion. That this might not always be the case is suggested by the results of Jacobs *et al.*[6]. They reported a series of quite obvious differences between the permeability of the red cells of rats and mice. One of these differences was the rather rapid rate of penetration of thiourea into mouse cells as compared with rat cells. Since these data suggest that the thiourea permeability of mouse erythrocytes might be another example of a "special case", the present experiments were performed to check this point.

Rat (*Rattus rattus* and *R. norvegicus*) and mouse (*Mus musculus*) blood were obtained by decapitation, the blood being collected in a large volume of isotonic, phosphate-buffered sodium chloride solution without anticoagulant. The cells were washed three times with this solution. Permeability measurements were made using a densitometer[7]. A portion of mouse cells was added to 0·3 M thiourea in water with and without butanol and the rate of haemolysis was measured at 0° C. Since the perm[illegible] of rat cells to thiourea is considerably lower, it w[illegible] to use volume-change measurements with [illegible] They were equilibrated in a solution of 0·[illegible] buffered, isotonic sodium chlorid[illegible] measured by adding a [illegible]

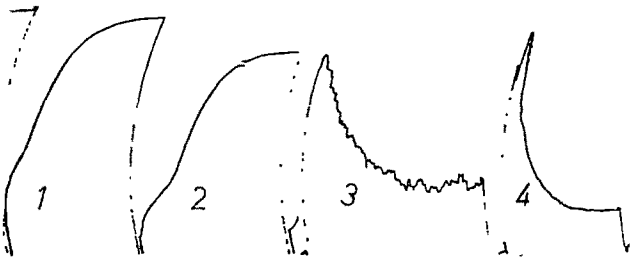

Fig. 1. Effect of butanol on the permeability of mouse and rat erythrocytes to thiourea. 1, Haemolysis of mouse cells in 0·3 M thiourea. 2, Haemolysis of mouse cells in 0·1 M butanol in 0·3 M thiourea. 3, Shrinking of rat cells, previously equilibrated in thiourea, in sodium chloride solution. 4, Shrinking of rat cells, previously equilibrated in thiourea, in 0·2 M butanol in sodium chloride solution

rat cells to thiourea in the presence of butanol has already been reported[4]. The decrease in the permeability of mouse cells to thiourea in the presence of butanol has not been reported, but is what would be expected if the permeability of these cells to this non-electrolyte represents another example of a "special case" of permeability.

Other data included by Jacobs *et al.*[6] suggest that in addition to glycerol[4], ethylene glycol and urea permeability in rat cells represent additional "special cases". To test this point the effect of butanol on the permeability of these cells to the three non-electrolytes was also investigated. Concentrations of 0·1 and 0·2 M butanol were investigated. Glycerol permeability was measured using the shrinking technique at 30° C. Ethylene glycol permeability was measured at 0° C by both the shrinking and haemolysis techniques, while haemolysis measurements at 0° C were used to investigate the permeability to urea. Relative times were calculated by dividing half the total time for the experimental curve by half the total time for the control curve. Thus, a relative time greater than unity indicates a decrease in permeability, while a relative time less than unity indicates an increase. The following relative times were obtained: glycerol, 6·3; ethylene glycol, shrinking, 3·7; haemolysis, 2·4; and urea, 1·4.

These data indicate that the permeability of at least mouse erythrocytes to thiourea is decreased by butanol just as this substance decreases the permeability of red cells of several species to glycerol. In addition, butanol decreases the permeability of rat cells to glycerol, ethylene glycol and urea. According to the interpretation suggested in ref. 5, facilitated diffusion appears to be involved in these four cases. Thus, to Fig. 8 of ref. 5 a right-handed symbol (facilitated diffusion-butanol inhibition) should be added to the urea group for the rat, to the ethylene glycol group for the rat, to the thiourea group for the mouse and to the glycerol group for the rat.

The experiments were performed in the Biology Department, University of the Andes, Bogotá, Colombia. We thank the Rockefeller Foundation for a grant in support of this work.

Sulphydryl Reagents and Rh Activity of Erythrocyte Stroma

IT has recently been shown that the Rh activity of lyophilized human Rh-positive stroma could be abolished with certain sulphydryl reagents, that this could be prevented by the concurrent addition of excess thiol, and that the loss was reversible with one such reagent[1]. It was not established whether the antigenic activity of non-lyophilized erythrocytes shows such an effect. The resolution of this problem was hampered in the case of intact cells by the presence of soluble sulphydryl systems, including haemoglobin and glutathione[2], and in the case of non-lyophilized stroma both by the occlusion of these soluble components, and by the difficulty of quantitation of wet stroma. The results of the present experiments suggest that the loss of Rh activity of lyophilized stroma brought about by sulphydryl reagents is equally true of stroma which has not been lyophilized.

Two methods of obviating occlusion were used. The first may be termed a *p*H shuttle, and consisted of washing the intact cells in 0·9 per cent sodium chloride, rupturing in distilled water, adjusting the *p*H under continuous monitoring to 8·3 with trisodium phosphate, then adding citric acid to *p*H 5·5, followed by centrifugation. The residue was then taken up in 15–20 times its volume of distilled water and the process repeated. At the higher *p*H the suspended phase assumed approximately colloidal dimensions and occluded material was released. Five or six such shuttle steps were required and it was noted that some loss of Rh activity resulted. A second method was then used which did not appear to result in loss of activity. Rapid freezing at the temperature of solid carbon dioxide was substituted for the *p*H shuttle, and the material was washed with distilled water. The freeze-thaw procedure was repeated twice.

Using stroma washed with the freeze-thaw method a fine uniform suspension was made up volumetrically in distilled water, a measured portion removed, lyophilized and weighed, and the relation between dry weight and volume calculated. Twenty mg of the lyophilized suspension was matched with the corresponding volume of non-lyophilized stroma. The samples were washed with 0·1 M sodium phosphate buffer (*p*H 7·0), centrifuged and treated with 10^{-4} M *p*-chloromercuribenzoate (Nutritional Biochemicals) in the same buffer for 60 min at 22° C with agitation. A similar set was treated with phosphate buffer only. The experiment was repeated using 3×10^{-4} M reagent. The specimens were then centrifuged, washed twice with phosphate buffer, and 1 or 2 ml. human isoimmune anti-D suitably diluted in normal human serum were added. The dilution was standardized so that 20 mg of untreated O Rh positive lyophilized stroma could just remove all anti-D activity after 60 min incubation at 37° C, and subsequent centrifugation. Similarly for the present experiments the supernatants after centrifugation were studied for residual anti-D activity against trypsinized O positive erythrocytes, as previously described[1]. The results are summarized in Table 1. The partial loss of activity with the lower concentration of *p*-chloromercuribenzoate and the complete loss with the higher concentration were indistinguishable from non-lyophilized stroma. In each case it was noted when 0·1 M [illegible] (Nutritional Organic) was present [illegible] results of similar [illegible] (Nutritional [illegible]

on the lyophilization process itself. These results show that such sensitivity does not depend on lyophilization. Freezing of intact erythrocytes without drying is not associated with significant disruption under certain circumstances[4] and it would not be anticipated that freezing and thawing of stroma would result in changes comparable to lyophilization. The present investigation does not show whether the Rh antigen of the intact erythrocyte is capable of reacting with sulphydryl reagents.

This investigation was supported by grants from the National Institute of Arthritis and Metabolic Diseases, National Institutes of Health and the National Foundation.

I thank Gary L. Rodney for technical assistance.

Copper Transport in Mammalian Tissues

RECENTLY, Neumann and Silverberg[1] presented results of experiments which were very similar to those which we had briefly reported earlier[2,3]. They concluded that amino-acids facilitate the transport of copper at the cellular level and presented conclusive evidence to support this. They further concluded that the facilitation of copper transport by amino-acids fulfils the criteria of an "active transport system", as it is dependent on temperature, concentration and oxygen, and operates against a chemical concentration gradient.

[illegible] believe that the latter conclusion cannot be based [illegible] evidence presented by Neumann and Silverberg. [illegible] two criteria, dependence on temperature and [illegible]ion, apply equally to the processes of simple [illegible]ion. Dependence on oxygen may [illegible]mical energy—but this is [illegible]en—the operation of

greater than 1·0 between the c.p.m./mg of tissue and the c.p.m./mg of medium during the incubation may simply be the result of a larger number of avid binding sites for copper in a unit weight of the slice as compared with the number in the unit weight of the tissue. Thus the possibility that the transfer of copper through the cell membrane occurs by diffusion or facilitated diffusion cannot be excluded on the basis of the results presented by Neumann and Silverberg.

In a paper quoted by Neumann and Silverberg, Ussing[4] states emphatically that the "definition (of active transport) excludes cases where a substance is concentrated in a cell by being bound to some cellular constituent as is the case with many dyes". He rightly regards it essential that the concentration of free, unbound ions should be known before one accepts that the maintenance of a chemical concentration gradient is meaningful in terms of the designation of a transport mechanism. Neumann and Silverberg did not measure the concentration of free Cu^{++} in the medium or the intracellular compartment.

It is for these reasons that we do not regard Neumann and Silverberg's claim that facilitation of copper transport by amino-acids fulfils the criteria of an "active transport" as having been proved. Their data and the results of similar experiments which we carried out do not exclude this possibility, but neither they nor we have as yet experimental proof of an active transport of copper.

Adsorption of Lactate Dehydrogenase to the Particulate Fraction of Homogenized Skeletal Muscle

WE have recently conducted an investigation of the factors involved in the release or retention of lactate dehydrogenase (LDH) from the particulate fraction of chicken breast muscle[1]. By appropriate procedures, we could effect essentially a complete release or retention. The major factors were the *p*H and ionic strength of the homogenization media; high *p*H and high ionic strength caused a greater solubilization of the enzyme. The influence of other factors could be explained in terms of their effect on *p*H and ionic strength. Adjusting conditions for the retention of LDH activity in the particulate fraction does not, however, establish that this enzyme occurs in a particulate or bound form *in situ*. Other possibilities such as co-precipitation, adsorption, and physical entrapment must be considered.

We had shown earlier that co-precipitation was not an important factor in the removal of LDH from the soluble fraction[1]. This was accomplished by creating in the absence of any particulate material the same conditions that allow extensive retention of LDH in the particulate fraction of a muscle homogenate after centrifug

Two points argue against any extensive co
of entrapment as an explanation for the partic
of LDH in crude homogenates. These are the
ness of recovery of LDH in the particulate fra
centrifuged homogenate which can easily be

Initially, it appeared that adsorption of soluble LDH to the particulate fraction during homogenization was extremely unlikely. We based this on two criteria. One was the almost complete association of LDH activity in the particulate fraction that can be obtained under certain conditions and the other was our observation that there was increased retention in the particulate fraction with a decrease in concentration of tissue[1]. It was necessary, however, to examine these phenomena more closely because of the sensitivity to *p*H and ionic strength of the distribution of the LDH between soluble and non-soluble components. Essentially, what we attempted to do was to mix solubilized LDH with particulate fractions of muscle from which the LDH had been removed under conditions that would duplicate as closely as possible those occurring when muscle is homogenized. We were interested in seeing whether we could get re-adsorption, whether the extent of re-adsorption would be sufficient to account for what we observe in homogenized muscle, and whether re-adsorption follows the same type of binding pattern, that is, increases with decreasing tissue concentration, as in homogenized muscle. In Table 1 the percentage re-adsorption of solubilized LDH to the particulate fraction of muscle is shown as a function of tissue concentration. The extent of rebinding is sufficient to account for the amount of LDH associated with the particulate fraction when muscle is homogenized, and, further, the pattern of binding with tissue concentration is the same. In these experiments we kept the ratios of LDH activity, buffer concentration, and amount of particulates constant. This would mean that the concentration of buffer in the final homogenate would decrease with decreasing tissue concentration and would imply that the final buffer concentration in the homogenate is the determining factor in re-adsorption and not the ratio of buffer to LDH or binding sites on the non-soluble fraction of the muscle homogenate. The *p*H was maintained at 6·6, at which value essentially no LDH would be removed by precipitation[1], and it is similar to the *p*H of many samples of homogenized chicken breast muscle.

In an attempt to distinguish between an adsorption of soluble LDH during homogenization (which certainly appeared possible from the data of Table 1) and location of LDH with the muscle particulates *in situ*, experiments were carried out to determine the distribution of LDH in muscle cell homogenates by differential centrifugation in two situations. In one, an LDH-rich particulate fraction was prepared by homogenization in water and centrifugation, while in the other the LDH-rich particulate fraction was obtained by re-adsorption of solubilized LDH to muscle particulates from which the LDH had been previously removed by salt. All other conditions of the procedures were kept constant. Table 2 summarizes the data obtained in one experiment. Other experiments gave comparable results. No major differences were observed between the two procedures in the distribution patterns regarding LDH or protein. The LDH activities

Table 2. DISTRIBUTION OF LDH IN VARIOUS SUBCELLULAR FRACTIONS FROM MUSCLE

Fraction	Specific activity of LDH (μmoles DPNH/min/mg protein)		Percentage of total LDH activity		Percentage of total protein	
	*A**	*B*†	*A*	*B*	*A*	*B*
Resuspended homogenate	6·7	5·7	—	—	—	—
S_1	3·0	3·0	4·4	5·9	10·9	12·0
R_1	6·9	5·8	34·6	39·5	36·0	41·0
R_2	8·1	6·9	46·4	36·2	41·0	31·0
R_3	7·9	4·6	6·2	7·5	5·6	10·0
R_4	3·4	3·8	0·3	0·3	0·6	0·6
S_4	11·8	14·7	7·7	5·9	4·8	4·4

* Sample *A* was prepared by homogenizing the muscle (10 per cent . w/v) in distilled water followed by centrifugation at 105,000*g* for 30 min. Almost all the LDH remains with the particulate fraction by this technique. The supernatant fraction was extensively dialysed against 15 mM histidine buffer, *p*H 7·0. Then enough solid sucrose was added to make it 0·88 M. The particulate fraction was then resuspended in this soluble fraction by homogenization in a Potter-type homogenizer. It was then centrifuged at 105,000*g* for 1 h. The supernatant fraction (S_1) was decanted. The residue was resuspended in 0·88 M sucrose, 15 mM histidine buffer, *p*H 7·0, and the following centrifugations were performed: 2,000*g* for 7 min (R_1); 15,000*g* for 10 min (R_2); 70,000*g* for 40 min (R_3); 105,000*g* for 60 min (R_4); the supernatant fraction from the final centrifugation was labelled S_4.

† Sample *B* was prepared by homogenization of a 10 per cent preparation in 150 mM sodium chloride followed by centrifugation at 105,000*g* for 1 h. This causes most of the LDH activity to go into the supernatant fraction. This fraction was dialysed extensively against 15 mM histidine, *p*H 7·0, and then enough sucrose was added to make it 0·88 M. The residue was washed twice by rehomogenization and centrifugation in 150 mM sodium chloride and 15 mM histidine, *p*H 7·0, respectively. It was then taken up in the dialysed supernatant fraction, rehomogenized and subjected to the same differential centrifugation as described for sample *A*.

LDH activity was determined by the procedure of Wu and Racker (ref. 6). Protein was determined by a biuret procedure (ref. 7).

The total LDH recovered was 78 per cent for both samples *A* and *B*. The protein recovered was 72 per cent in both cases.

of sample *B* were somewhat lower than those of *A*, which may possibly have been caused by the extended dialysis of the LDH of sample *B*. We conclude from this that the pattern of rebinding of soluble LDH to the non-soluble muscle fraction is similar to that obtained when the muscle is homogenized directly under conditions which lead to retention of the enzyme. In other words, not only the extent of retention but also the distribution of LDH among various subcellular fractions of muscle homogenized under conditions conducive to retention could possibly be attributed to adsorption of soluble enzyme to the particulate fraction after homogenization. The capacity of the muscle particulate fraction in binding LDH is considerably greater than the amount of LDH normally present in the tissue. We have prepared LDH-rich particulate fractions which have bound more than six times the quantity of LDH originally present.

We cannot say definitely at this time on the basis of our results whether LDH exists as a soluble cytoplasmic enzyme, is bound to subcellular fractions, or exists in an equilibrium between soluble and non-soluble phases. Several reports using a cytochemical approach have indicated that LDH is bound to the subcellular structures of muscle[2-4], and Amberson *et al.*[5] arrived at a similar conclusion by a different approach. In view of the high binding capacity of the particulate fraction of muscle, any investigation which purports to show the particulate nature of muscle LDH must take into account the possibility of adsorption of a soluble enzyme.

L-Lysine Dehydrogenase Deficiency in a Patient with Congenital Lysine Intolerance

RECENTLY, a new metabolic defect, which was believed to arise from congenital lysine intolerance, was described in a 3-month-old baby girl[1]. An enzymatic impairment in the pathway for the degradation of lysine seemed the most probable explanation of the main finding, that is, high plasma lysine levels. Because the enzymes responsible for the metabolism of lysine in human beings had not previously been investigated, efforts were made to find an enzyme system capable of degrading lysine. This report presents evidence for the existence of a hitherto unknown enzyme, L-lysine: nicotinamide-adenine dinucleotide (NAD) - oxidoreductase (deaminating) (trivial name: L-lysine dehydrogenase) in human liver homogenates.

Fresh human liver was cut into small pieces, added to four parts of a 0·05 M *tris*-buffer (*p*H 8·8) and homogenized in a glass Potter homogenizer with a loose fitting glass pestle. The homogenate was centrifuged at 1,500*g* for 3 min and the clear supernatant used for enzymatic assay after dilution with nine parts of buffer. The standard incubation medium contained: 0·4 ml. 0·95 M L-lysine in 0·05 M *tris*-buffer (*p*H 8·8), 0·05 ml. of a 0·06 M NAD-solution, 0·02 ml. 0·05 M cysteine and 0·3 ml. of the 1 : 50 homogenate. The reagent blank contained buffer instead of substrate. After pre-incubation of the mixtures in a 37° C water bath for 10 min, the formation of $NADH_2$ was measured in an Eppendorf photometer at a wavelength of 366 nm at 37° C and recorded with a W+W recorder. Enzyme activities were calculated and expressed in μmoles lysine metabolized per minute. Experiments were also performed without cysteine at 25° C, as with increasing temperature the activity decreased.

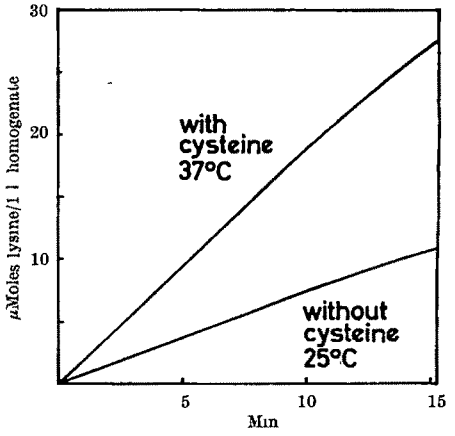

Fig. 1

As can be seen from Fig. 1, a linear relationship exists between the amount of lysine metabolized and time. The presence of cysteine results in a two- to three-fold increase in activity. These results strongly suggest that the proposed reaction[2,3]:

L-lysine + NAD + H_2O → α-keto-ε-amino caproic acid + $NADH_2$ + NH_3

is catalysed by a specific deaminating amino-acid de-[redacted]ase with NAD acting as hydrogen acceptor. [redacted]timal conditions had been established, liver [redacted] of the patient was assayed for lysine de-[redacted]e activity. The results are summarized in [redacted]d indicate a deficiency of L-lysine: NAD-

oxidoreductase. Because a defect of this enzyme results in clinical hyperlysinaemia it is suggested that in man the first step in lysine degradation is achieved by oxidative deamination.

α-Glycerophosphate Dehydrogenase in Mouse Adrenal Cortex

IN the adrenal cortex of the mouse, non-NAD-linked α-glycerophosphate dehydrogenase can be demonstrated in the mitochondria and shows an interesting distribution which is different from that of the Krebs cycle enzymes.

Sections of adrenals from mature mice were cut and frozen-substituted using the method of Chang[1]. The distribution of mitochondrial non-NAD-linked α-glycerophosphate dehydrogenase was found by the histochemical method of Farber[2]. It was observed that this enzyme is confined to the zona glomerulosa of the adrenal gland (Fig. 1). Companion sections stained for succinate dehydrogenase activity showed the latter enzyme, and thus the activity of the Krebs cycle, to be more intense in the fasciculate and reticular zones and comparatively faint in the glomerular zone (Fig. 2).

It has been suggested that non-NAD-linked α-glycerophosphate dehydrogenase plays a part in the utilization of reduced NAD generated outside the mitochondria and that it is part of a system alternative to lactic dehydrogenase which maintains a high rate of glycolysis. It thus seems likely that the glomerular zone of the mouse adrenal cortex depends on glycolysis for a major part of its energy requirements compared with the fasciculate and reticular zones, which apparently depend more on the Krebs cycle activity as a source of energy.

It may be added here that the adipose tissue around the adrenal capsule also shows a high α-glycerophosphate dehydrogenase activity. A similar high enzyme activity has been reported by Farber[3] in the adipose tissue about the kidney.

Identification of 1-(o-Carboxyphenylamino)-1-deoxyribulose and Anthranilic Acid in Cultures of the Basidiomycete *Schizophyllum commune*

IN the course of investigation of indigo biosynthesis in mutant strains of *Schizophyllum commune*, these strains were found to produce a number of interesting compounds which were released into the medium. Both the pigmented strains (130 and 2456) and the non-pigmented strains (699 and 2417) were grown either in flasks on a shaker or in a carboy with aeration. A minimal medium was used containing in each litre of distilled water: 20 g glucose, 1·5 g $(NH_4)_2HPO_4$, 120 μg thiamine hydrochloride, 0·46 g KH_2PO_4, 1 g K_2HPO_4 and 0·5 g $MgSO_4.7H_2O$. After filtering through cheese cloth to remove the mycelium, the medium was brought to *p*H 4·0 with 0·1 N hydrochloric acid and extracted with an equal volume of ethyl acetate. A dark red material was obtained after drying the extract overnight over anhydrous sodium sulphate and concentrating it by distillation at 35° C under vacuum to about 3 ml.

Chromatography of the extract resulted in the detection of two unknown compounds which showed an intense blue fluorescence under ultra-violet light. Chromatography on Whatman No. 1 paper, using several solvents and location reagents (2 per cent dimethylaminobenzaldehyde (PABA) in 80 ml. acetone and 20 ml. hydrochloric acid, and dimethylaminocinnamaldehyde (DMCA) in 90 ml. acetone and 10 ml. hydrochloric acid, both applied by dipping) showed that one of the unknown compounds was identical to natural anthranilic acid (Table 1), while the results with the second unknown compound indicated it to be 1-(*o*-carboxyphenylamino)-1-deoxyribulose (CDR)* (Tables 2 and 3).

* Abbreviations used: CDRP, 1-(*o*-carboxyphenylamino)-1-deoxyribulose-5-phosphate; AA, anthranilic acid; PRA, *N*-(5′-phosphoribosyl) anthranilic acid; InGP, indolyl-3-glycerol phosphate; CDR, 1-(*o*-carboxyphenylamino)-1-deoxyribulose.

CDR was extracted from ethyl acetate with phosphate buffer at *p*H 7·7. Hydrolysis with 1 N sodium hydroxide at 100° C for 5 min[1] resulted in breakdown of CDR and appearance of anthranilic acid, due to cleavage of the molecule. This alkaline lability is expected from an Amadori compound[2].

The extract of *p*H 7·7 was also used in the preparation of 2,4-dinitrophenylhydrazone of CDR. Addition of 0·5 per cent 2,4-dinitrophenylhydrazine in 2 N hydrochloric acid to the buffer extract resulted in the formation of an orange precipitate after standing overnight at room temperature. The ethanol-washed precipitate was used for ultra-violet absorption spectroscopy. At *p*H 7·7, the absorption spectrum (taken with a 'Beckman *DB*' spectrophotometer) was similar to those obtained from a hydrazone derivative of a synthetic CDR by Doy and Gibson[3] (Fig. 1).

Even though synthetic CDR was not available in this experiment, the colour reactions (especially with alkaline 2,3,5-triphenyl tetrazolium chloride), the behaviour during alkaline hydrolysis and the ultra-violet absorption spectrum clearly show that CDR is produced by pigment-producing strains of *S. commune*. Neither CDR nor anthranilic acid was found in strains that lacked the pigment. CDR was suggested by Yanofsky[4] as a possible intermediate in the tryptophan pathway and was later identified in a culture medium of mutant strains of *Aerobacter aerogenes*, *Escherichia coli*[3,5] and *Salmonella typhimurium*[5], all blocked at various stages in tryptophan synthesis. On the other hand, strains of *S. commune* that produce CDR and anthranilic acid do so on minimal medium without addition of any intermediate of tryptophan biosynthesis. It is possible that the presence of CDR in the culture medium of pigmented strains of *S. commune* results from a partial block between indolyl-3

glycerol-phosphate and 1-(*o*-carboxyphenylamino)-1-deoxyribulose-5-phosphate that brings about an accumulation of CDRP and *N*-(5′-phosphoribosyl) anthranilic acid. The lability of PRA is increased by acid and decreased by alkali[6]. In acid, PRA undergoes spontaneous hydrolysis to anthranilic acid and ribose-5-phosphate. Such a partial block will result in the accumulation of anthranilic acid and the non-phosphorylated form of CDRP, that is, CDR (ref. 7). The same pigmented strains that accumulated CDR and anthranilic acid were also found to accumulate indolyl-3-acetic acid[8]. It might indicate that anthranilic acid and CDR can participate in reactions other than those that lead to tryptophan synthesis.

I thank Dr. Philip G. Miles for his help and encouragement throughout the work, and Dr. Willard B. Elliot for his guidance and advice.

Early Effect of Ethionine on Liver Affinity for Iron

INCREASED affinity for iron by the liver was shown to occur *in vivo* and *in vitro* when ethionine was fed to animals from 1 to 3 weeks[1–3]. After 3 weeks of feeding ethionine there was a change in the affinity of the liver for iron, so that by 4 weeks there was no significant difference between the experimental and the control animals. By 6 weeks the affinity effect had been reversed by the liver so that the animals treated with ethionine had a decreased affinity when compared with the controls. The purpose of the present experiment was to determine the changes in the affinity before 1 week of ethionine treatment, as it is known that changes in the liver occur

Table 1. LIVER AFFINITY FOR IRON (C.P.M./G LIVER EXPRESSED AS A PERCENTAGE OF STANDARD)

Duration of experiment	No. of rats	Experimentals Mean	*S.D.*	Controls Mean	*S.D.*	Significant level
12 h	12	2·44	0·30	2·81	0·50	$P = 0·05$
1 day	9	3·34	0·58	4·13	0·99	$P < 0·05$
2 days	9	3·78	0·50	3·91	0·70	$P > 0·05$
3 days	10	4·86	0·54	4·24	0·56	$P < 0·05$

very rapidly after feeding ethionine[4,5]. The present experiments were designed to observe any possible changes in affinity shortly after the administration of ethionine and to correlate this with certain morphological and histochemical changes observed previously[5].

Male albino rats of the Sprague–Dawley strain were used, each weighing approximately 300 g. They were fed a synthetic diet containing 18 per cent casein[2] by way of tubes. The experimental animals received 0·5 per cent *d,l*-ethionine in the diets, and in the control animals the ethionine was omitted. Each animal in the first group received 3·5 g of the diet 12 h before killing. The other animals—those killed after 1, 2 and 3 days—received 10·5 g of diet per day in three divided feedings over 12 h periods during the day and they fasted for 12 h before being killed. Livers were removed, sliced, and incubated in 15 ml. of Ringer's solution containing 10 mc. iron-59 in the form of ferrous sulphate. The method of incubation was identical to that described previously[2]. Liver slices were then removed, washed in 15 ml. Ringer's solution for 0·5 h and then counted in a well-scintillation counter. The results were expressed as percentages of the standard, which was 2 ml. of the original incubating fluid counted for 1 min. The data were analysed using Student's *t* test for paired-comparisons. Because of the design of the experiment, comparisons could be made only between experimental and control values at any given interval, but not between different intervals.

The data shown in Table 1, and the mean difference in iron uptake between the experimental and control groups for each interval, are plotted in Fig. 1. Twelve h after ethionine feeding, the radioactive iron uptake in the liver was lower in the experimental than in the control animals. However, the difference in affinity was considered to be statistically marginal ($P = 0·05$). By 1 day, the affinity of the liver of ethionine fed animals for iron was significantly less than in the controls ($P < 0·05$). However, by 2 days there were no statistically significant differences between the experiments and controls ($P > 0·05$). By 3 days the livers of ethionine-fed animals showed an increase in the affinity for iron ($P < 0·05$). This increase is similar to that seen at subsequent periods up to 3 weeks[2,3].

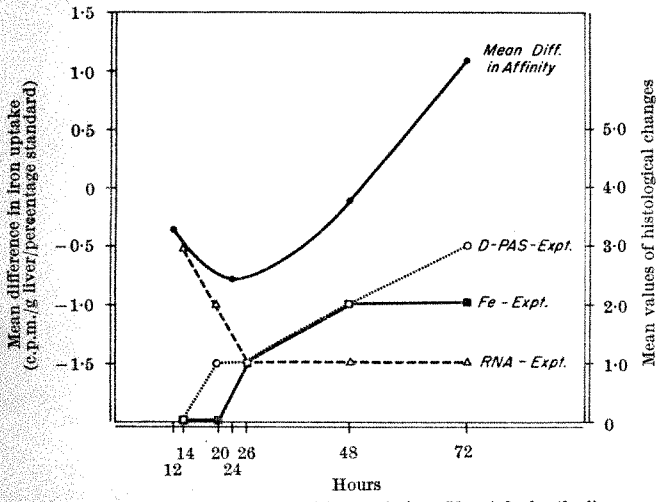

Fig. 1. Comparison of the mean difference in iron-59 uptake by the liver between experimental and control animals at different intervals, with changes in histochemically demonstrable RNA, DPAS-positive material and iron

An attempt was made to correlate the changes in the affinity of the liver for iron during the early stages of ethionine administration with the alterations in the histochemically demonstrable RNA, diastase resistant, periodic acid–Schiff (DPAS)-positive material and iron in the liver[5]. This was performed by assigning arbitrarily 1+ to each degree of change in RNA, DPAS-positive material, and iron observed previously[5] and plotting this against the presently observed changes in affinity (Fig. 1). It can be seen that at the times when there was maximal decrease of RNA and initial increase in DPAS-positive material and iron, the affinity for iron in the ethionine-fed animals was lower than in the controls. This occurred at 12–26 h. Afterwards there was increased affinity associated with further increase in both DPAS-positive material and iron, but no further changes in the histochemically demonstrable RNA.

The initial depression of liver affinity for iron corresponds to the reported rapid inhibition of protein synthesis[6,7]. It corresponds also with the maximum decrease of histologically demonstrable RNA in the liver[5] (Fig. 1). It is tempting to speculate that the decreased affinity for iron in the liver at an early interval of ethionine administration is associated with depressed synthesis of apoferritin along with the general inhibition of protein synthesis[6,7]. However, some of our recent data indicate that apoferritin synthesis may not necessarily parallel other protein synthesis[8].

On the basis of the intimate association of iron deposition and development of DPAS-positive material[5], it has been suggested that the DPAS-positive material that develops before iron deposition is associated with the increased affinity for iron[2]. However, the initial increase of DPAS-positive material and the initial appearance of histochemically demonstrable iron[5] corresponds to a decreased affinity of the liver for iron in the present experiment (Fig. 1). Furthermore, after prolonged ethionine feeding a decrease in liver iron[9] was noted at a time when affinity was decreasing[3], while a DPAS-positive material was still present in abundance. From this it would appear that other additional factors are at play or that the DPAS-positive material represents a situation with changing physical–chemical properties.

Rapid Column Chromatography of Purine and Pyrimidine Bases on 'Ectaola' Cellulose at Room Temperature and Elevated Pressure

A NUMBER of methods have been published for the column chromatographic separation of the purine and pyrimidine bases[1]. The shortcomings of these are their slow rates of flow and the fact that the separations require up to three days. In view of the biochemical importance of these

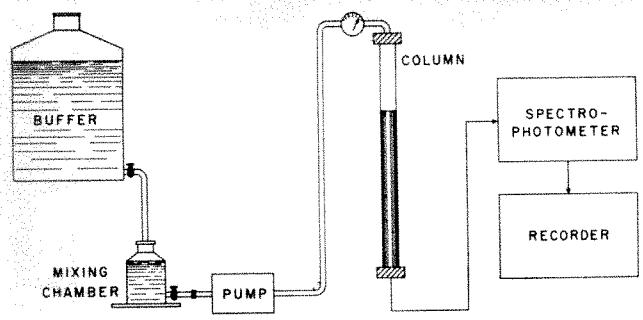

Fig. 1. Diagram of gradient elution system

heterocyclic components, faster techniques for their quantitative estimations are needed.

After testing various ion exchangers, namely, 'Dowex', 'Amberlite', and 'Sephadex', for their efficiency of separation, we found that 'Ectaola' cellulose achieved the most satisfactory results. 'Ectaola' has previously been used for column chromatography of nucleic acids[2] as well as for the thin-layer chromatography of nucleic acid derivatives[3]. A modification of these methods was used in the present work. It involves a gradient elution procedure at slightly elevated pressure and allows the separation of the five chemically most important bases in about 60 min at the 10^{-10} molar level. Less common bases and the nucleic acids may also be separated by this technique over longer periods of time.

In principle, the procedure uses a buffer gradient system of (1) 1 N sodium chloride in ammonium hydroxide and ammonium chloride at *p*H 10·60, and (2) distilled water adjusted with hydrochloric acid to a *p*H of 2·75. All liquids have sufficiently low density in the range of 240–290 mμ.

The major steps of the method are illustrated in Fig. 1. From the buffer reservoir containing a sodium chloride buffer, a continuous flow is supplied into the mixing chamber filled with buffer at *p*H 2·75. A magnetic stirrer provides effective mixing of the two buffers which are then pumped through the ion-exchange column at constant rates of flow, giving a linear gradient elution pattern. The absorption characteristics of the eluant are finally measured with a Gilford spectrophotometer (model 2000).

The ion-exchange column consists of a high-pressure nylon tube 65 cm in length and 0·5 cm in inner diameter, filled with a slurry of 200–325 mesh of 'Ectaola' (Brown Co., Berlin, New Hampshire) for the lower 45-cm section. The upper 20 cm of the column are only provided to hold sufficient ammonia for the column regeneration after each run. Care has to be taken that no air is trapped in the resin or introduced during the loading of the column.

Each analysis is preceded by the introduction of 8 ml. of ammonium hydroxide and ammonium chloride buffer *p*H 10·60 (ionic strength 0·2) which is followed by 10 ml. of the *p*H 2·75 buffer. This provides an increased hydroxyl ion retention by moving from top to bottom of the column[4].

For calibration a standard mixture of purine and pyrimidine bases (2·5 μmoles/ml.) dissolved in sodium hydroxide (*p*H 10·6) is added to the column. The sample is allowed to penetrate the top layer of the resin bed. Afterwards, the upper 20 cm of the column is filled with the *p*H 2·75 buffer; after all connexions are secured, the analysis is started. The tubing from the mixing chamber to the top of the nylon column holds exactly 20 ml. of *p*H 2·75 buffer. The salt gradient is established by a constant supply of the sodium chloride buffer (*p*H 10·60) to the mixing chamber containing exactly 125 ml. of *p*H 2·75 buffer. The pump is set at a flow rate of 96 ml./h; this results in a back pressure of about 35 lb./in.^{2}. A complete development of the five common nucleotide bases is accomplished in less than 90 min (Fig. 2). The spectrophotometric measurements are taken at 260 μm.

To locate the position of the individual base, each compound is run separately. It should be pointed out that the positions of uracil and thymine are almost identical (Fig. 2) when run separately. To achieve a separation between these two bases an extended equilibration of the column with ammonium hydroxide (6 h) and at a faster rate of flow (120 ml./h) is recommended (Fig. 3). To test application of the method outlined to biochemical research, the bases of hydrolysed DNA and RNA are recorded in Fig. 4. Aside from the common bases of both nucleic acids, three additional peaks appeared on the elution chromatogram; they are marked by the Roman numerals I–III. They correspond to the positions of methyl-cytosine (I), uric acid (II), and hypoxanthine (III). The areas under the peak can very easily be used for the quantitative determination of each base present in the sample. Because the Gilford spectrophotometer records the data in a linear fashion and the peaks are perfectly shaped, a simple digital integrator can simultaneously print out the area under the peaks as they emerge from the column. The recovery of each component is in the range 95–100 per cent.

In summary, a pressure-gradient-elution technique for rapid and quantitative separation of the purine and pyrimidine bases is presented. The separation of the bases can be achieved within 60 min at room temperature. The precision is better than 5 per cent for the individual

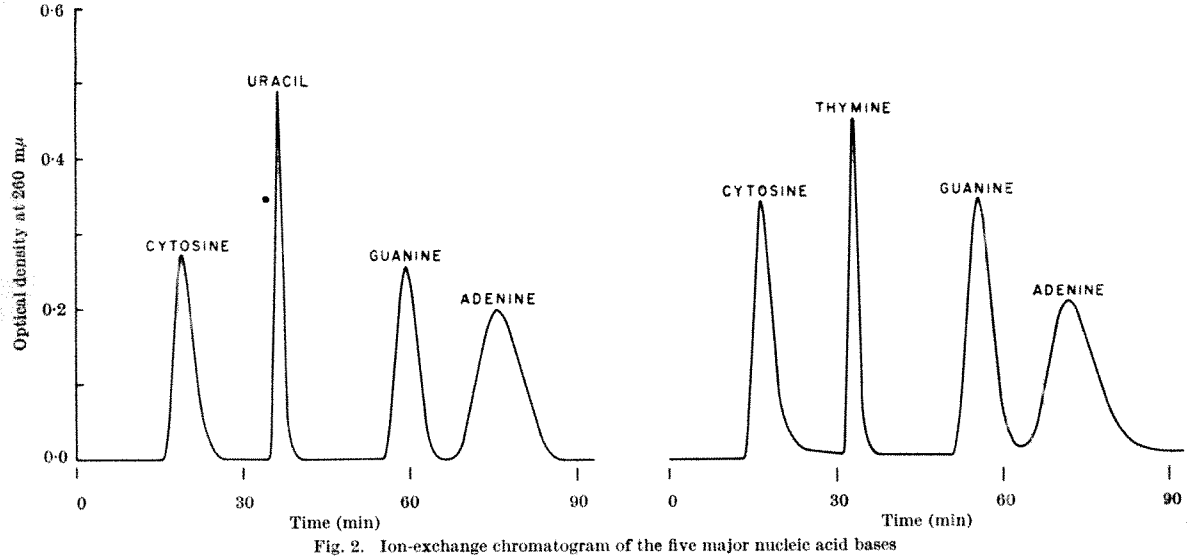

Fig. 2. Ion-exchange chromatogram of the five major nucleic acid bases

base at the 10^{-10} molar level. The wide application of this technique to biochemistry and related sciences is obvious.

Chemical Nature of the Pigment Spots of *Enoplus communis*

AT the anterior end of the free-living marine nematode *Enoplus communis* are situated two pigment spots, dark red-brown in life. Their superficial appearance is very reminiscent of eye-spots. Schultz[1] suggested that these pigment spots were excretory granules and were not in any way associated with photoreception.

Unlike the eye-spots of some marine nematodes, there is no lens structure or well-defined perimeter. The pigment is localized in two lateral pockets inside the oesophageal tissue, and having posterior to the pigment spots diffuse areas of granular pigment which extend back through the oesophageal tissue.

In an attempt to characterize the pigment, a number of solvolysis experiments were carried out, and specific bleaching reagents used. The pigments were fixed in formalin and were found to be readily soluble in concentrated sulphuric acid; they were, however, wholly insoluble in concentrated hydrochloric acid. The pigments disappeared in normal sodium and potassium hydroxides in a few minutes. They were quite unchanged in such organic solvents as diethyl-ether, chloroform, benzene, acetone and xylene. They did not dissolve in ethylene chlorohydrin, but this is only specific after separation from the protein component[2].

After dissolving the spots in concentrated sulphuric acid, there was a partial return of the colour on diluting with water[3].

Strong bleaching was found in concentrated and 50 per cent nitric acid and weak bleaching was recorded with solutions of hydrogen peroxide (6 per cent, w/v), potassium dichromate (2·5 per cent, w/v), and potassium permanganate (1 per cent, w/v)[4,5].

These results, together with the dark brown colour and granular consistency, strongly suggest that the "eye-spot" is melanin, and is therefore unlikely to be involved directly in photosensitivity.

Occurrence of D-Lysergic Acid and 6-Methyl-ergol-8-ene-8-carboxylic Acid in Cultures of *Claviceps purpurea*

OVER the past few years we have been examining the composition of ergot alkaloids produced *in vitro* by strains of *Claviceps purpurea* isolated from sclerotia growing on grasses in England. It was noted that exhaustive chloroform extraction of culture filtrates adjusted to *p*H 8·5

removed only about 40 per cent of the total Ehrlich-positive material; the remaining material at *p*H 3·5 was readily extracted with *n*-butanol. Paper[1,2] and thin-layer[3] chromatographic analysis of the chloroform-soluble fraction showed chanoclavine to be the principal component present accompanied by small quantities of elymoclavine and the ergotoxine group. Chromatography of the butanol fraction revealed only one fluorescent, Ehrlich-positive spot which was inseparable from D-lysergic acid and 6-methylergol-8-ene-8-carboxylic acid, the isomer of lysergic acid recently obtained from cultures of *C. paspali*[4]. We now have re-examined culture filtrates of a strain of *C. purpurea* originally isolated from *Spartina townsendii* to investigate further the composition of the butanol fraction.

The fungus was grown in submerged culture on a rotary shaker (200 r.p.m., 10 cm eccentric throw) at 24° C in 500 ml. Erlenmeyer flasks containing 100 ml. of the following medium modified from Stoll *et al.*[5] (values in per cent): calcium nitrate, 0·1; epsom salt, 0·025; potassium dihydrogen phosphate, 0·025; potassium chloride, 0·0125; $FeSO_4.7H_2O$, 0·0033; $ZnSO_4.7H_2O$, 0·0027; sucrose, 10; asparagine, 1; cysteine hydrochloride, 0·001; yeast extract, 0·01; distilled water, *p*H 5·0. Maximum alkaloid production (100 μg/ml.) was reached within 10 days.

One litre of culture filtrate adjusted to *p*H 8·5 was extracted with chloroform (3 × 500 ml.) and then, at *p*H 3·5, with *n*-butanol (3 × 500 ml.). The residue obtained from the butanol extracts (142 mg) was applied to 20 g of 'Zeo-karb 225 (H^+)' ion exchange resin and, after washing with water, the fluorescent band was eluted with 1 M ammonium hydroxide to give 66 mg of an off-white solid. The ultra-violet absorption spectrum showed that the principal chromophore present in this material corresponded to that of the $\Delta^{8,9}$-acid (λ_{max}287 mμ) although some absorption in the region of lysergic acid (λ_{max}312 mμ) was also observed.

Following the procedure outlined by Kobel *et al.*[4], the crude material from the ion exchange column was esterified with methanolic hydrochloric acid and the resulting mixture reduced with lithium aluminium hydride in anhydrous tetrahydrofuran. In this way 15 mg of solid was obtained which on thin-layer chromatography in two systems[3,4] showed two Ehrlich-positive spots, one fluorescent and corresponding to lysergol standard, and the other non-fluorescent and corresponding to elymoclavine standard. Together with the other evidence presented, identification of these reduction products clearly established the presence of lysergic acid and 6-methylergol-8-ene-8-carboxylic acid in the original extract. This is the first time that the $\Delta^{8,9}$-acid has been demonstrated as a *C. purpurea* metabolite. D-Lysergic acid, in trace amounts, has previously been reported[6] in culture filtrates of mixed cultures of *C. purpurea* and a *Claviceps* sp. isolated from *Pennisetum typhoideum* but, to our knowledge, the present investigation gave the first identification of D-lysergic acid in pure cultures of *C. purpurea*.

We thank Dr. J. Rutschmann of Sandoz, Ltd., Basle, for kindly supplying a pure sample of the $\Delta^{8,9}$-acid.

Nutritive Values of Shrimp Flour

THIS communication presents some new data and ideas concerning the chemical constituents and potential uses for shrimp of the south Atlantic Ocean, and points the way to further systematic investigations of the links in selected food chains, such as that of phytoplankton→zooplankton→fishery resources.

The shrimp, *Artemesia longinaris* Bate, which feeds on plankton, inhabits shallow waters from southern Brazil to Argentina; it enters the commercial catch off Mar del Plata, Argentina. Specimens were collected with a coarse plankton tow net from the Argentine R.V. *Zapiola* in March 1965 off Mar del Plata. The average wet weight of these animals was 2·73 g. The meat was separated by hand from the shells and heads of 138 individuals, and the components frozen and dried in a vacuum drying oven. Afterwards, the meat and shells were prepared for chemical analysis (Food and Drug Research Laboratories, Maspeth, Long Island, N.Y.) by grinding them separately to a fine meal in a Wiley cutting mill. The shrimp meal had a pleasing yellow colour, an attractive smell, and rich flavour. Such qualities could possibly help to make this material acceptable for protein enrichment of soups, bread, crackers and other foodstuffs.

The dry matter in the crude whole shrimp was about 32 per cent of the wet weight. The hard chitinous shells together with the heads and other attached matter amounted to 14 per cent of the original wet weight. Thus 18 per cent of the fresh shrimp could be converted to dry meat. The approximate composition of the dried shrimp meat and shells is given in Table 1. The calculated protein of the whole dried shrimp (65·6 per cent, or 21 per cent of the wet weight) is comparable with the protein content of lean beef, ox liver, salmon or turkey.

The amino-acid constituents of the meat and shell portions of the shrimp were determined by column chromatography, after acid hydrolysis, according to the general methods developed by Moore, Spackman and Stein[2]. It was found to be necessary to assay cystine microbiologically[3] owing to the fact that losses of this amino-acid were encountered in the ion-exchange procedure with the shrimp meat hydrolysate. Alkaline hydrolysis of portions of the samples was performed when the materials were prepared for tryptophan analysis[4].

Amino-acid profiles of shrimp meat and shells are shown in Table 2. The glycine and valine content of the shells was higher than in the meat, while cystine, histidine, methionine, and tryptophan were more abundant in the

meat. It is possible that the recovery of tryptophan was incomplete in the analyses. Comparison of the amino-acid profiles in the meat of *A. longinaris* Bate with that of the common canned shrimp[5] sold throughout the United States shows that they have a similar composition. In this respect it would also be of interest to make a similar analysis of the common krill (*Euphausia superba* Dana and other species) which is abundant in the Antarctic seas. In Antarctica, krill occupies the intermediary link in the food chain from primary phytoplankton to whales (or penguins). Because of the decline in whaling, it would be advantageous to focus special attention on the crustaceans formerly eaten by whales, with the view of utilizing this abundant supply of food for man. It has come to our attention[6] that in the Philippines shrimp shells are ground into a powder, mixed with flour and eggs, and fried to make a crisp delicacy. This would suggest that the chitinous materials could be put to some use when whole shrimp powder becomes available for human use. It is hoped that chemical and nutritional investigations on krill and other unconventional sources of marine foods will find application in the production of protein enrichments for the human diet.

We thank the Vetlesen Foundation and the National Science Foundation for financial support. We also thank Captain Ricardo Bustamente of the Servicio de Hidrografia Naval, Buenos Aires, Argentina, for helping in the collection of the crustacea.

Electrophoretic Fractionation of Heat-denatured Eucollagen

IN the early stages of collagen fibrogenesis, soluble forms of collagen can be extracted with salt solutions; as the tissue develops, dilute acids and acidic buffers are needed. Eventually these reagents also become ineffective as a relatively insoluble form of collagen is elaborated. This transformation or "maturing" is believed to be caused by an increase in the number of intramolecular and intermolecular cross-links[1].

Soluble material can be obtained from this mature collagen by a preliminary treatment with cold alkali. As a result of this, it is possible to dissolve in this medium a large proportion of the collagen that was previously insoluble in citrate buffer (*p*H 3·7). Such alkali-treated collagen is called "eucollagen"[2]. This communication reports the preparation and electrophoretic analysis of eucollagen solutions prepared from the shin tendons of cattle.

The flexor tendons from the shin of a calf foetus, a 3–4-month-old calf and a 14-month-old steer were frozen, comminuted, immersed in liquid nitrogen for a few seconds and then shattered in a percussion mortar and pestle. The neutral salt-soluble collagen was removed by extraction in solution of sodium chloride. Each sample was extracted for 24 h in a cold solution of sodium chloride, after which the mixture was centrifuged at 1,500*g* for 30 min. The tissue residue was then removed, ground with sand in the cold, and then subjected to extraction procedures for two further periods—the first for 5 days, and the second for 24 h. The supernatant was removed by centrifugation at 1,500*g* for 30 min at each stage, and all extractions were carried out at 4° C.

The tissue residue that remained after the extraction with sodium chloride was then washed twice with cold water, and the acid-soluble collagen was extracted from it by two periods of treatment in citrate buffer (*p*H 3·7, 0·15 M). Each extraction lasted 3 days and was performed at 4° C. On each occasion the tissue residue was removed by centrifugation at 1,500*g* for 30 min.

After extraction of the acid-soluble collagen the tissue residue was washed twice with cold water and used for the preparation of eucollagen. The method used was essentially that described by Higgs and Reed[3]. Unless otherwise stated, the stages of preparation were carried out at room temperature. They were as follows: (*a*) the samples were allowed to stand overnight at 20° C in a saturated solution of sodium sulphate; (*b*) 5 days at 20° C in 5 per cent sodium hydroxide saturated with sodium sulphate; (*c*) three successive treatments, each for 1 h with saturated solutions of sodium chloride; (*d*) 1 h treatment with saturated solutions of sodium chloride containing sufficient acetic acid to bring the *p*H to 6·0; (*e*) 4 h standing in distilled water the *p*H of which was adjusted to 6·0; (*f*) two 12-h period of standing in distilled water *p*H 6·0 at 5° C; (*g*) four successive immersions each lasting 2 days, in 0·15 M citrate buffer (*p*H 3·7) at 8° C; (*h*) a fifth extraction in 0·15 M citrate buffer (*p*H 3·7) for 2 days at 8° C. These procedures provided a solution of eucollagen, which was then centrifuged for 30 min at 2,000*g* to remove any large debris, and finally used for electrophoretic analysis.

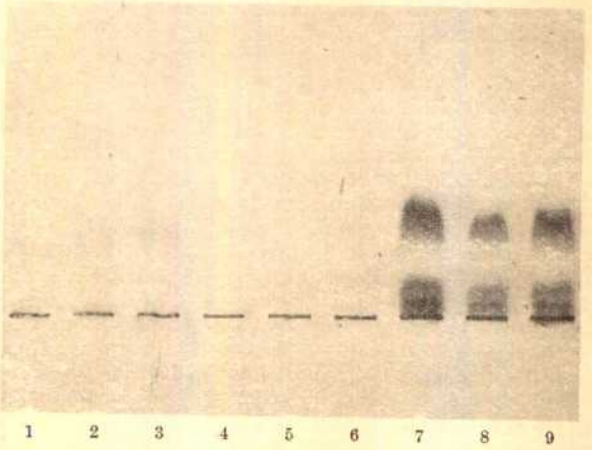

Fig. 1. Samples 1–3. Eucollagen prepared from the shin tendons of a 3–4-month-old calf. Samples 4–6. Eucollagen prepared from the shin tendons of a calf foetus. Samples 7–9. Eucollagen prepared from the shin tendons of a 14-month-old steer

In the electrophoretic study a discontinuous buffer system was used in the vertical apparatus described by Smithies[4]. A gel was prepared with 10 per cent starch and 5 per cent urea in a buffer which consisted of 0·1 M glycine brought to *p*H 3·0 (at 20° C) with lactic acid. This was poured into the end sections of the apparatus, and when the gel had set, a second gel which contained 12 per cent starch and 5 per cent urea in a buffer of 2 mM aluminium lactate (brought to *p*H 3·0 (at 20° C) with lactic acid) was poured into the centre section.

Before electrophoresis the eucollagen solution was dialysed for 12 h against the aluminium lactate buffer containing 0·5 M sucrose; and then incubated at 37° C for 30 min immediately before the application of the samples to the starch gel. Electrophoresis was carried out at 2° C for 7 h at 400 V, 25–30 m.amp.

The results are shown in Fig. 1. They demonstrate the separation achieved by this electrophoretic technique,

and that formation of insoluble collagen increases as the animal approaches maturity.

Utilization of Adenine but not Nitrate as Nitrogen Source by *Prototheca zopfii*

CULLINMORE[1] has recently reported that *Prototheca zopfii* (Cambridge Collection strain No. 263/5) will utilize butyrate as the sole carbon source for growth, but only after a lag period of 3 days. It is presumed that this represents a period of enzyme induction. We have been investigating some aspects of the nitrogen metabolism of this strain of *Prototheca* and have observed that while adenine can be used as the sole nitrogen source there is again a lag period before growth commences. In this case, however, the lag is only about 30 h. (Fig. 1). The increase in dry weight obtained suggests that ring nitrogen of the adenine molecule is utilized in addition to the amino group.

Pure cultures of *Prototheca zopfii* were grown in 100-ml. Erlenmeyer flasks containing 20-ml. of the medium used previously[2], but with the ammonium nitrate omitted and with the addition of 1 per cent glucose and 10^{-5} M thiamine[3]. 140 mg nitrogen/l. was then supplied either as ammonium sulphate, potassium nitrate or adenine. After autoclaving, the *p*H of the medium was 6·1. The flasks were inoculated under aseptic conditions and were shaken in darkness at 25° C. The dry weight of algae in cultures was determined by means of sintered glass filter crucibles dried in an oven at 80° C.

Inorganic nitrogen assimilation by *Chlorella vulgaris* has been extensively studied and it was shown that the activity of the nitrate reductase is inhibited by ammonium assimilation[4] and further that the synthesis of the enzyme is repressed by ammonium[5]. We assumed that this situation might apply to *Prototheca zopfii*, which is generally considered to be a colourless *Chlorella*[6], and were interested to determine whether adenine as well as ammonium would repress the production of nitrate reductase. However, a preliminary experiment showed that the alga is unable to utilize nitrate as sole nitrogen source as is shown in Fig. 1. We are not fully convinced that this observation is previously unrecorded but in the investigations known to us the alga was grown in media which contained either ammonium chloride or ammonium sulphate as nitrogen source. This derives from Barker's[7] original work in which a medium containing ammonium chloride was used and the significant observation was made that growth was still dependent on the addition of small quantities of yeast extract owing to the requirement for thiamine[8].

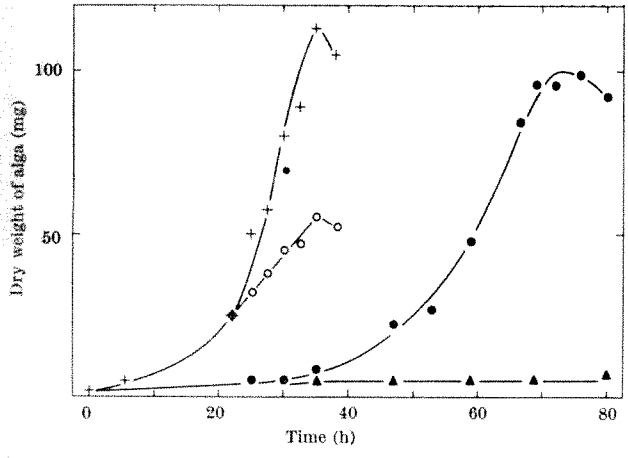

Fig. 1. Growth of *Prototheca zopfii* with various nitrogen sources in the medium. +, 140 mg N/l. as ammonium sulphate; ○, 28 mg N/l. as ammonium sulphate; ●, 140 mg N/l. as adenine; ▲, 140 mg N/l. as potassium nitrate

It has been suggested that the fact that *Prototheca zopfii* contains a definite plastid[9,10] implies that it arose from a mutation rendering it incapable of synthesizing chlorophyll[10]. At present it is not known whether the alga is unable to synthesize nitrate reductase, as in the case of the *Chlorella* mutant isolated by Shafer *et al.*[11], or whether nitrate assimilation is actually blocked at the stage of nitrite reductase. In *Ankistrodesmus*[12] the nitrate reductase requires as coenzyme reduced nicotinamide adenine dinucleotide ($NADH_2$) and the nitrite reductase reduced nicotinamide adenine dinucleotide phosphate ($NADPH_2$). The latter enzyme is particulate. Similarly, a nitrite reductase requiring ferredoxin has been associated with chloroplasts isolated from several higher plants[13]. Thus there seems to be a definite possibility that the inability of *Prototheca* to utilize nitrate is associated with the absence of a functional chloroplast. If this is indeed the case the biochemical differences between *Prototheca* and *Chlorella* are more complex than the inability to synthesize chlorophyll, and as a consequence carbohydrate by photosynthesis, would indicate. The assimilation of ammonium by yeast leads to a stimulation of the pentose phosphate pathway of glucose oxidation to satisfy the requirement of the glutamic dehydrogenase for $NADPH_2$ (ref. 14). Although it is quite clear that *Prototheca zopfii* is capable of degrading glucose by this pathway[15] a comparable coupling to nitrogen metabolism may not have developed.

AGRICULTURE

Incidence of *Rhizoctonia* in a Cultivated and a Fallow Soil in Hong Kong

THE arable land available in Hong Kong is very limited and farming is so intensive that the annual production of 8–9 vegetable crops, often on the same land, is common. For many reasons, especially from an accumulation of soil-borne pathogens, this might be expected to have a deleterious effect on the soil.

A comparison[1] of the fungi present in a cultivated and in a fallow soil using Warcup's soil-plate method[2] indicated that at least two genera of fungi which are known to be causal agents of soil-borne diseases were more prevalent in the cultivated soil. *Pythium* sp. was only isolated from the cultivated soil. Whereas the occurrence of *Fusarium dimerum* was high in this soil, it was seldom found in the fallow soil.

Because it was rarely possible to isolate the common soil fungus *Rhizoctonia* by this method, a modification of the method devised by Papavizas and Davey[3] was used instead. Mature lima bean (*Phaseolus vulgaris* L.) stems were flushed in running tap water for 1–2 min, immersed in a 10 per cent solution of bleaching powder for 30 sec, and then washed in sterile water. The stem internodes were then cut into 1/8 in. segments, and buried in samples of freshly collected cultivated and fallow soils (stored in glass troughs). After incubation at 23°–24° C for 3 days, the stem segments were washed first in tap water to remove the attached soil particles and then in five changes of sterile water in a Griffin's electric shaker for 2 min. The stem segments were then damp-dried between sheets of sterile blotting paper and transferred to plates of 2 per cent water agar. Any fungal colonies growing out from the stem segment after 24 h incubation at 23°–25° C were sub-cultured on PDA plates[3]. In general, because only one small colony appeared after such a short incubation period, one isolation was made from each stem segment.

During June–August 1964, a total of 260 stem segments were plated out for the two soils. The results showed that, whereas 41 per cent of the lima bean stem segments taken from the cultivated soil were colonized by *Rhizoctonia*, only 2·7 per cent of the segments from the fallow soil were infected. It thus became clear that *Rhizoctonia* was far more abundant in the cultivated soil than in the fallow soil.

It is tempting to suggest that cultivation of the soil resulted in the build-up of *Rhizoctonia* but evidence to support this is lacking. Moreover, the pathogenicity of both *Rhizoctonia* and the other possible pathogenic genera isolated in the previous study[1] has not been established as yet. There were no serious outbreaks of any soil-borne disease in the intensively cultivated cabbage fields. The reasons for the absence of disease are not known; it is possible, however, that the micro-organism was not pathogenic, or that it was not sufficiently virulent. Unfavourable weather conditions or perhaps resistance of the crop may also have played a part.

An Attempt to predetermine the Sex of Calves by Artificial Insemination with Spermatozoa separated by Sedimentation

BHATTACHARYA[1,2] has described a method for separating from rabbit semen two fractions of sperm with which he achieved a significant degree of predetermination of sex. He suggested that the separation depends on the tendency of the female producing *X*-sperm to sediment more rapidly than the male-producing *Y*-sperm, when the sperm are rendered immotile by cooling to 1° C and then allowed to sink under the influence of gravity for 12 h through a column of a viscous egg yolk medium. This communication describes briefly the results of experiments designed to examine the applicability of Bhattacharya's technique to cattle.

Specimens of about 1·5 ml. of semen from either Hereford or Friesian bulls were provided by the Cambridge Cattle Breeding Centre. After 24 h for treatment at Babraham to separate the fast and slowly sedimenting spermatozoa, samples from the top and bottom of the columns were given code numbers and returned to Cambridge. For the first series of separations an egg yolk/glycerine medium ('*A*') was used, in conjunction with the glass apparatus described by Bhattacharya[2]. Later separations were carried out in a milk/glycerol medium ('*B*'), with an apparatus consisting of a stack of stainless steel sheets drilled with holes to form columns which could be fractionated by sliding the sheets sideways. Between November 1964 and July 1965, 411 cows were inseminated with fractionated semen (24 h old), and 191 of them became pregnant, giving a conception rate of 46·5 per cent. A control group of inseminations using untreated semen from the same collections gave 192 pregnancies in 310 cows, a conception rate of 61·9 per cent. The 191 test pregnancies yielded 153 calves of known sex, of which eight were twins; in forty-two cases the sex of the calves was not reported, usually because of sale of the cows before calving. A comparison of the predicted and actual sexes of 139 of these calves is given in Table 1. Fourteen returns (eight males and six females) were excluded from the analysis, either because a non-standard technique was used (for example, medium '*A*', but the stainless steel apparatus), or because sperm counts made after the semen had been dispatched to the inseminators showed that there was doubt whether the samples were the best representative 'top' or 'bottom' fraction. Of the twins, there was one pair of males and one pair of mixed sex in each of the two categories, medium '*A*' predicted female, and medium '*B*' predicted male. In 136 calves of the control group the sex of which was returned, there were sixty-nine males and sixty-seven females.

Table 1. SUMMARY OF CALVING RESULTS

Technique	Predicted sex	Actual sex
Medium '*A*', glass apparatus	Male	12 M 18 F
	Female	32 M 31 F
Medium '*B*', stainless steel apparatus	Male	12 M 11 F
	Female	13 M 10 F
Medium '*B*', deep freeze method	Female	15 M 19 F
	Total	84 M 89 F

Another batch of thirty-seven heifers was inseminated in San Francisco in August and September 1965. The semen was allowed to sediment in glass tubes containing medium '*B*', and the bottom fraction was selected after the column had been quickly deep frozen. All the heifers became pregnant, but twenty of them had to be inseminated twice or more with the fractionated semen. The animals were slaughtered after 35–60 days of pregnancy, except for one which was allowed a normal delivery. The sex of the foetus was determined from a macroscopic inspection of the primary sex organs, except for three rejected cases where development was incomplete. As can be seen in Table 1, the sex distribution was again not very far from equality.

Although in these experiments the predictions were not successful, subsequent work has indicated that the techniques used here for differential sedimentation may not be entirely free from disturbing factors, and by applying slightly modified methods Schilling[3,4] has apparently obtained greater success in predetermining the sex of calves. Further biological tests of the significance of the variation in sedimentation velocity among spermatozoa are clearly needed.

We acknowledge the help of Mr. H. J. Ballinger, who collected and analysed many of the data.

Observations on the Parthenocarpic Response of Blueberry to Gibberellic Acid

IT was previously noted[1,2] that the lowbush blueberry, *Vaccinium angustifolium* Ait., will respond to gibberellic acid (GA) placed on the open flower, by the formation of parthenocarpic fruit. It has not been possible to effect the same response in the field on any broad scale. The reasons for this are not understood, but some evidence has been obtained to suggest that certain clones are more receptive to GA than others. The period of receptivity to the growth substance is also well defined and the parthenocarpic fruits seem to swell up more slowly than do seeded berries.

Because in a practical field operation there is no possibility of excluding pollinating insects, only a limited experiment could be established to determine whether application of GA curtails normal fertilization or whether the opposite effect occurs.

Vegetative cuttings in the greenhouse were induced to flower by subjecting them to a regimen of 8 h of light per day[3]. When flowering became general in eleven clones, freshly opened flowers were selected, unopened buds and older flowers were excised, and one of the following treatments was administered: (1) treatment with water (controls); (2) hand pollination; (3) treatment with GA in water (50 p.p.m.); (4) sprayed with 50 p.p.m. GA, and 24 and 48 h later hand pollinated; (5) hand pollinated and 24 and 48 h later sprayed with GA at 50 p.p.m.

Table 1. RELATIONSHIP BETWEEN SEED CONTENT AND PHYSIOLOGICAL AGE

	Early	Late
No. of berries	121	40
Percentage of seedless	2·5	62·5
No. of seeds	3,462	153
Mean seeds	28·6 (29·3)	3·8 (10·2)*

* Bracketed numbers include only fruits with seeds.

Table 2. RELATIONSHIP BETWEEN SEED CONTENT AND TREATMENT

Treatment	Fruits	Seeds	Distribution of berries with respect to seed content 0	10	11–30	+30	Mean No. seeds per fruit
(1)	2		2	—	—	—	—
(2)	50	1,412	—	10	20	20	28·2
(3)	23	50	16	5	2	—	2·5
(4)	28	907	—	5	11	12	32·4
(5)	58	1,238	10	11	20	17	21·3

When the fruits matured, increased in size and changed colour, they were harvested and seed counts were made weekly (June 4–July 17). These data are presented as early fruit (harvested before June 15) and late fruit (harvested June 16–July 17) in Table 1. The seed content of fruits harvested from the various treatments is shown as Table 2.

The early fruit was heavily seeded, while the berries maturing later generally contained fewer seeds. The data of Table 1 indicate that only three berries that formed parthenocarpically had matured sufficiently for the early harvesting. None the less, treatment with GA resulted in a greater set response (84·3 per cent) than did hand pollination (62·3 per cent). Between the time when the set was estimated (14 days after treatment) and the date of harvesting, 58 per cent of the GA-induced fruits were lost. When the flowers were sprayed with GA and pollinated 24 or 48 h later, no parthenocarpic fruits were formed but ten seedless berries resulted from the application of GA subsequent to hand pollination.

The results of this work support the finding[4] that physiological maturity in the blueberry is expedited by increased fertilizations. Furthermore it would seem that the stimulus to form fruits parthenocarpically from GA either is not quantitatively sufficient to permit ripening within the season, or incompletely substitutes for the natural stimulation to form berries that follows fertilization. These possibilities are indicated both by the lateness of maturing of the seedless fruits and by the high wastage of set berries.

GA can thus induce parthenocarpic response in the blueberry; however, it seems clear that the response that follows the application of this compound does not duplicate (at least in its entirety) the natural "berry-building" processes that stem from pollination and fertilization. Also the force of the response to GA depends on the clone treated.

These data support other observations that suggest a considerable variability in the setting of fruits in *V. angustifolium*. One clone at Tower Hill, New Brunswick, has never set fruit. Another produces large fruits, usually with a low seed count (4·2 seeds/fruit, this experiment). Some clones are natural parthenocarps.

BIOLOGY

Influence of Oestrogen on the Loss of the Zona Pellucida in the Rat

IN the rat, the fertilized egg normally loses its zona pellucida about 10 h after it reaches the uterus. Blastocysts flushed from the uterine cavity before 12 a.m. on the fifth day after the onset of a positive smearing reaction are still surrounded by their zonae, but those flushed in the early afternoon of the fifth day have lost their zonae[1–3]. Implantation begins some 6 h after the loss of the zona (110–114 h after ovulation)[1].

When the ovaries are removed before noon on the fourth day of pregnancy, the blastocysts do not implant, but the zonae disappear at the normal time—that is on the afternoon of day 5. Blastocysts of ovariectomized animals treated with 5 mg progesterone also lose their zonae at this time and do not seem to differ from those of normal or untreated ovariectomized animals.

If the ovaries are removed on day 2 of pregnancy, however, and the rat is treated with 5 mg progesterone per day, the zona pellucida persists until the eighth day of pregnancy. In this period the blastocyst assumes a spherical shape owing to the enlargement of the embryonic cavity. On day 8 these blastocysts rupture their zonae but do not implant until oestrogen is given together with the progesterone. Unless oestrogen is supplied, the ruptured zona persists undissolved in the uterine cavity. The dose of oestrogen (17-*b*-oestradiol) required to bring about the dissolution of the zona is less than that (0·05 mg) required for implantation.

These results show that oestrogen is necessary for the dissolution of the zona pellucida in the rat. The loss of the zona pellucida at the normal time in animals ovariectomized on day 4 of pregnancy suggests that small quantities of this hormone are produced before the fourth day of pregnancy. The results also suggest that delayed implantation is not related to the persistence of the zona pellucida.

Chromosome Abnormality in Cattle

RECENTLY, a chromosome abnormality found in three cases of lymphatic leukaemia in cattle was described[1]. This communication reports my latest findings concerning this abnormality. It appears that in Sweden cattle chromosomes have only once before been investigated using modern techniques. On that occasion Melander[2] found the chromosome number in animals of the Swedish breed *SLB* to be 60; all autosomes were characterized by having strictly terminal centromeres. The existence of telocentric chromosomes has now been verified in several groups of animals including cattle[3–6].

In order to obtain further information on the chromosomes of *Bos taurus* in Sweden, animals belonging to the Swedish breeds of *SLB* and *SRB* from mid and southern Sweden were studied. Using a modified form of the blood tissue-culture technique[7], counts were soon made of the chromosome numbers of 1,134 animals. Eighty-nine per cent appeared to have 60 chromosomes, a figure which agreed with previous counts (Figs. 1 and 2). One hundred and twenty-two animals were found to possess a complement of 59 chromosomes of the type mentioned above[1], and a number of bulls were included in this group (Fig. 3). In four bulls, only 58 chromosomes were found per cell (Fig. 4). All the animals which were investigated appeared normal and some of the bulls have since been used for artificial insemination purposes. Until now only animals of the *SRB* breed have been found with this chromosome abnormality.

It would appear that the chromosome abnormality found in these cattle is a case of intraspecific chromosomal polymorphism. This type of variation—centric (chromosome) fusion, or translocation of the Robertsonian type—is relatively common in invertebrates[8–11]. It may exist in the lizard *Gerrhonotus scincicauda*[12], and it has also been described in some mammals.

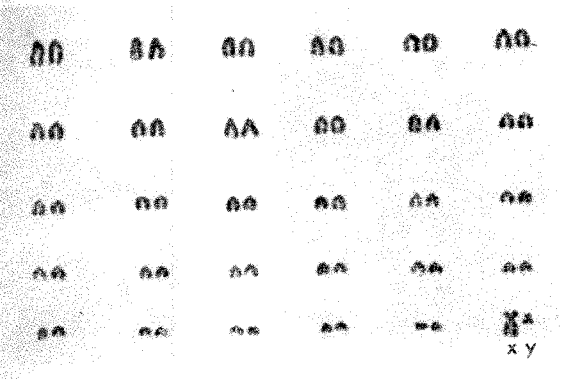

Fig. 1. $2n = 60$, male. The autosomes have been arranged as nearly as possible according to decreasing size. (× 900)

Fig. 2. $2n = 60$, female. The autosomes have been arranged according to decreasing size. (× 900)

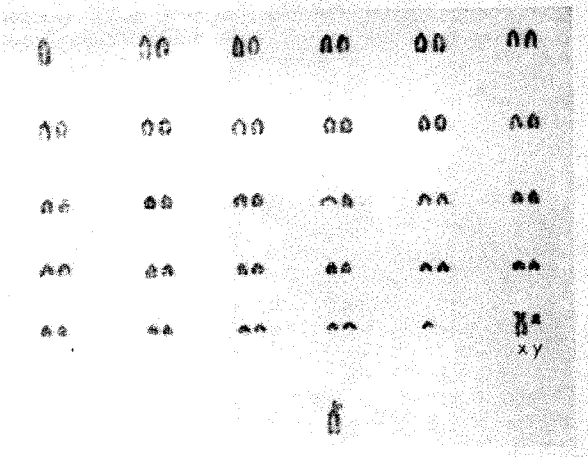

Fig. 3. $2n = 59$, male. Note that two telocentric chromosomes are replaced by a long subtelocentric chromosome. (× 900)

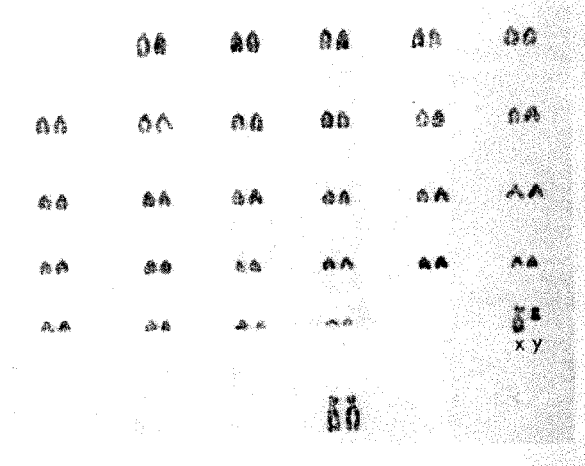

Fig. 4. $2n = 58$, male. Instead of two telocentric chromosome pairs, a subtelocentric chromosome pair is present. (× 900)

The first example of the abnormality in mammals was described in *Sorex araneus*. Besides an XY_1Y_2 sex chromosome system in the male[13], extensive studies have revealed two races, one monomorphic and one polymorphic. The number of chromosomes varies between 21 and 31, but the number of chromosome arms remains constant[14–17].

Though the European genus *Mus* seems to be cytogenetically uniform, the African sub-genus *Leggada* contains both inter- and intra-specific variation of the centric fusion type. Recently, Matthey[18] found chromosome numbers 31, 32, 33 and 34 in the species *M. minutoides musculoides*. This constitutes a typical Robertsonian system. Another species, *M. triton*, appeared to have a rather more complicated translocation system than the Robertsonian pattern[19]. In *M. minutoides minutoides* from South Africa the complements consisting of 18 and 19 chromosomes were observed. Some animals with 18 chromosomes had an $N.F. = 36$, thus all chromosomes were bi-armed. In the same population individuals were found with an $N.F. = 35$. This reduction resulted from a pericentric autosomal inversion. Cytologically, this species only differed from another species or sub-species from the same area, *M. minutoides indutus* ($2n = 36$), by translocations of the Robertsonian type. Furthermore, Matthey suggests that "this mixed population is the last phase of a previous polymorphic system splitting in two species in

statu nascendi". On this basis it is possible to get sympatric speciation resulting from chromosomal mutations. This theory contradicts one proposed by Mayr[20], who claims that groups require to be geographically isolated from each other before speciation can occur.

Intra-specific chromosome polymorphism was reported previously in *Gerbillus pyramidum*[21] and *Acomys cahirinus*[22]. However, hybridization experiments revealed that there are reproductive barriers between the different cytogenetic types, which indicates that an advanced stage in speciation has been reached by both groups[23].

In a study of some species of *Acomys*[23], Matthey observed two chromosome numbers in the members of a race of *A. minous*. A metacentric chromosome was found to be the cause of the difference; this would appear to represent a more complicated type of polymorphism than that explained by the Robertsonian type.

Centric fusion of telocentric chromosomes is a common characteristic of neoplastic tissues[24] and is frequently found in cells in tissue culture[25-26]. As outlined by White[8], and also pointed out by Ohno *et al.*[25], a translocation of this type is of adaptive significance because new gene complexes are formed with different recombination values relative to the position of other gene loci. Little or no loss of genetic material is thought to occur and the number of chromosome arms is constant as is the DNA content per nucleus.

The Robertsonian type of chromosome translocation which we have described in cattle is the first example of this type of rearrangement observed in domestic animals.

Cuticular Structure in the Phalangida

APART from passing references such as that of Kastner[1] to the cuticle of *Trogulus*, there is no information about the cuticular structure of the Phalangida. Histological investigations of the cuticle in three species of the Palpatores revealed a marked difference between the cuticle of the dyspnoic *Nemastoma lugubre* (Mull) and the two eupnoic species *Leiobunum rotundum* (Lat.) and *Phalangium opilio* Lin.

In the two eupnoic species the situation is closely comparable with that of insects[2] and scorpions[3]. In cuticle with an overall thickness of 14μ there is an endo-cuticular component 9μ thick and an exo-cuticle 4μ thick. The boundary between these two components is sharp and comprises an area which has little affinity for aniline blue, orange *G* or acid fuchsin. It is perhaps comparable with the amber, or quinone tanned, exo-cuticle of scorpions[3,4]. The endocuticle differs from the relatively homogeneous exo-cuticle in its laminate structure. These laminae have a strong affinity for aniline blue and a slight residual affinity for acid fuchsin. In addition to these two major components there is, on the sclerites, an epi-cuticular layer corresponding to the cuticulin of the epi-cuticle in scorpions. This is bordered externally by further thin epi-cuticular components.

In the arthrodial membranes the exo-cuticle is absent and they comprise a 2μ heterogeneous epi-cuticular component overlying the strongly laminate endocuticle which is uniformly stained by aniline blue.

In contrast the thick cuticle of *Nemastoma lugubre* comprises numerous laminae which are closely and regularly packed in the external 3·5μ but less so in the internal 19μ. In neither of these regions do the laminae have any marked affinity for the foregoing stains. The most internal laminae do, however, have a slight positive reaction with acid fuchsin. Throughout the body the external closely packed laminate region contains the melanin which gives the species its characteristic colour. This is only lacking in the region of the two white spots.

In general the staining reactions of the arthrodial membranes, in which the epi-cuticular component is acid fuchsin positive and the endo-cuticular component aniline blue positive, compares with the condition in other arthropods. In view of the fact that the endocuticle of *Phalangium* and *Liobunum* is also aniline blue positive with a residual affinity for acid fuchsin, it would seem that sclerotization only affects the exo-cuticle. The limitation of the acid fuchsin positivity in *Nemastoma* to the innermost lamina suggests that in this genus which, together with the Cyphophthalamae, Laniatores and Trogulidae, has long been known from superficial inspection to have a harder cuticle, this hardening is associated with the sclerotization of the entire thickness of the cuticle. It is further seen that in all three species the endo-cuticular component of the sclerites with its loosely laminated structure is more closely similar to the structure of the endo-cuticular component of the arthrodial membrane than is the case in scorpions where the laminae of the arthrodial membrane are more marked in adult animals than are those of the endocuticle.

'Wavy–Fused' Mutants in the Medaka, *Oryzias latipes*

AIDA[1] first reported the occurrence of *wavy* and *fused* vertebral mutations in the medaka. These characters are simple recessive to normal and are independent of all known genetic characters and sex. The vertebral column of the *wavy* fish curves dorso-ventrally (Fig. 1 *B*) and some centra of the *fused* fish are fused (Fig. 1 *C*). Fig. 1 *AD* show the backbones of normal and *wavy–fused* fish. Recently, Takeuchi[2] also reported a *wavy* mutant of the medaka which had appeared in the breeds of Yamamoto in Nagoya University and this mutant was used in the present experiment. Although the *wavy* mutant is a simple recessive, the way in which it expresses itself suggests the presence of modifiers of the principal gene. The *fused* mutant used here originally appeared in Aida's breed and has been kept in the laboratory of Yamamoto (Nagoya). A detailed

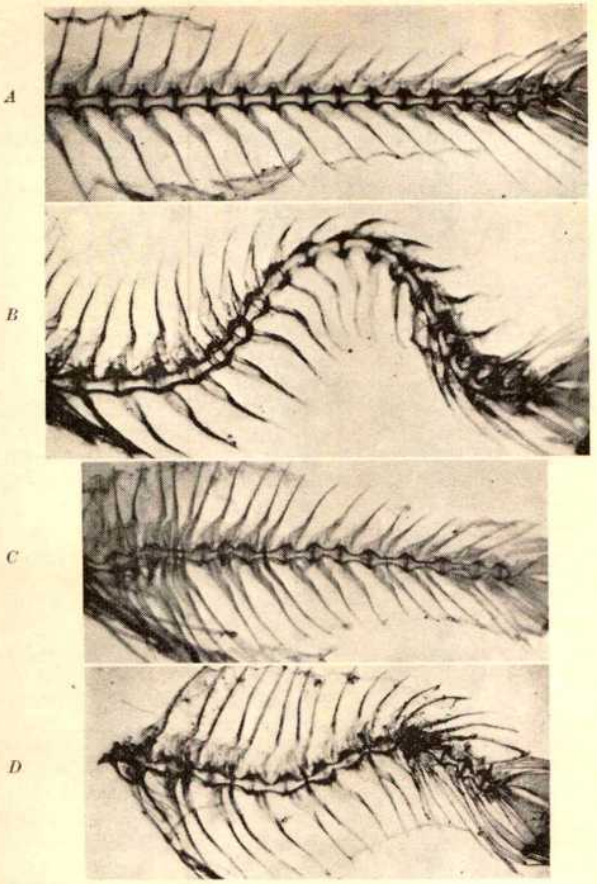

Fig. 1

genetic investigation of the *fused* mutants was performed by Yamamoto *et al.*[3].

Fishes were treated with 2 per cent potassium hydroxide for several hours and stained by alizarin *S* before they were examined under the microscope. The F_1 offspring of the male *wavy* mated to female *fused* was normal. Of 1,294 F_2 offspring, 885 were normal, 314 *fused*, 85 *wavy* and 10 *wavy–fused*. The ratio of normal plus *wavy* to *fused* plus *wavy–fused* is about 3 : 1 with a P value of 0·95. However, the ratio of normal plus *fused* to *wavy* plus *wavy–fused* is far from three to one ($P \ll 0{\cdot}01$). The result agrees with the earlier findings[2]. If the *wavy* and *fused* genes are on homologous chromosomes, the appearance of *wavy–fused* fish must arise from recombination, and the recombination fraction calculated from the number of F_2-offspring by the "maximum likelihood method"[4] is about 40 per cent. The value of the recombination fraction is unusually high and the foregoing hypothesis may not be true. The separation in F_2-offspring is better interpreted as follows: the *fused* and the main *wavy* genes are not on the homologous chromosomes. The relatively small numbers of *wavy* and *wavy–fused* offspring may arise from modifiers of *wavy* gene and the weakness of *wavy–fused* fish.

Control of Lateral Bud Inhibition, Flower Emergence and Dormancy in the Blackcurrant

IN south-east England vegetative growth in the blackcurrant starts in April and ceases in July or early August, by which time shoots are about 60 cm long, bearing from twenty to thirty buds which usually start to initiate flowers from late June onwards. Normally, they do not break until the following spring.

In the field, premature bud break during the summer can be observed in shoots with damaged growing points, or occasionally after extensive leaf fall caused by an early and severe attack of *Pseudopeziza ribis*. This suggested that apical dominance and/or the presence of leaves may contribute to the maintenance of buds in a quiescent state during the summer.

To investigate the role of these two factors, experiments were carried out on the variety 'Wellington *XXX*' during 1964 and 1965.

Treatments consisted of either complete defoliation of whole bushes or the removal of the apical 2 in. of each shoot at weekly intervals beginning on June 1 and June 15, respectively. In untreated control bushes extension growth, assessed by weekly measurement, had ceased by July 15.

The results of these two experiments are summarized in Table 1 from which it will be seen that both treatments cause buds to break. Defoliation, however, is conspicuously more effective than decapitation. In the earlier defoliations bud break was distributed throughout the length of the shoots; following later treatments, however, there was a tendency for it to be restricted to the upper region only. By contrast, decapitation allowed the top two or three buds only to break and these were situated immediately below the pruning cut. Decapitation was effective in inducing bud break only up to the time of cessation of extension growth whereas defoliation caused bud break for a further five weeks.

During the period of extension growth, therefore, natural inhibition appears to be caused by a combination of apical dominance and leaf inhibition. After extension growth ceases buds seem to be inhibited by effects emanating from the leaves rather than the apex. From the end of August, when lateral buds appear to have entered full winter dormancy, leaf removal failed to induce bud break. Once this stage has been reached under normal field conditions, an adequate period of chilling at temperatures below 45° F (ref. 1) is required to ensure bud break in the following spring.

These results suggest that, apart from the apical dominance effect, growth inhibitors may be synthesized in the leaves and passed back into the buds, thus playing the principal part in preventing their growth. The presence of substantial amounts of inhibitor was demonstrated by El-Antably[2] in short-day grown blackcurrants.

One of the striking results of the defoliation experiment was the fact that leaf removal allowed the newly initiated flowers to emerge within a few weeks of their formation. Clearly there is no specific inhibition of the flower buds; their failure to emerge in the first season would seem to

be linked directly with the general inhibition of lateral buds.

In the south-east of England, flower initiation in 'Wellington *XXX*' takes place just before the cessation of extension growth (ref. 3 and compare with ref. 4). In sectioned buds this was seen to have occurred by June 22 in 1964, that is 23 days before the cessation of extension growth. The first defoliation treatment (June 1) induced vegetative growth only, whereas defoliation on or after June 8 resulted in the emergence of flowers also. These observations suggest that the first irreversible steps towards flower initiation had already occurred in the buds 2 weeks before the first initials could be detected. This conclusion was supported by data obtained in 1965 when plants in the field were maintained in an actively growing condition by artificial illumination or gibberellic acid applied some weeks before extension growth of untreated bushes had ceased. Where the treatments were applied more than 2 weeks before the microscopically detectable onset of flower initiation (early July), the plants continued to grow vegetatively and flower initials were not observed when the buds were examined several weeks later. Buds of untreated control plants carried advanced initials at this time. Where treatments were applied less than two weeks before flower initiation was observed, flowers developed in the lower buds of treated plants despite the continuation of extension growth.

Biological Activity of Volatile Fungal Metabolites

A RECENT survey has measured the effects of volatile metabolites from sixty-two fungal cultures on chosen characters of growth and reproduction of five assay species, namely: *Rhizopus sexualis* (Smith) Callen, *Chaetomium globosum* Kunze ex Fr., *Stereum hirsutum* (Willd.) Fr., *Aspergillus niger* van Tiegh., and *Botrytis cinerea* Pers. ex Fr. The sixty-two species tested consisted of thirteen Phycomycetes, thirteen Ascomycetes, six Basidiomycetes and thirty Fungi Imperfecti, representing a wide range of habit. These species were tested using the simple apparatus shown in Fig. 1; each test consisted of a comparison of three replicate cultures, each containing the assay fungus on the upper agar plate and the test fungus on the lower plate, with three replicate controls each containing the assay fungus on the top plate and sterile agar on the lower plate.

In these conditions the gases from forty-one of the sixty-two species had a significant effect on the rate of increase of colony diameter of at least one of the assay species. Table 1 summarizes these observations.

The relatively crude measurements have not revealed any interactions affecting rate of increase of diameters of colonies of *R. sexualis*, but two test species (*Saccharomyces cerevisiae*, *Schizosaccharomyces octosporus*) produced at least twice the least significant inhibition of all the other four assay species; one (*Fomes annosus*) produced more than ten times the least significant inhibition of *C. globosum* and of *A. niger*, and almost twice the least significant inhibition of *S. hirsutum* and of *B. cinerea*. There were many more inhibitory than stimulatory reactions, and most of the stimulation was very slight.

Table 1

No. of species having a significant effect ($P = 0{\cdot}05$)	*Rhizopus sexualis*	*Chaetomium globosum*	*Stereum hirsutum*	*Aspergillus niger*	*Botrytis cinerea*
Inhibitory	0	11	15	4	19
Stimulatory	0	2	3	7	5
No measured effect	62	49	44	52	38

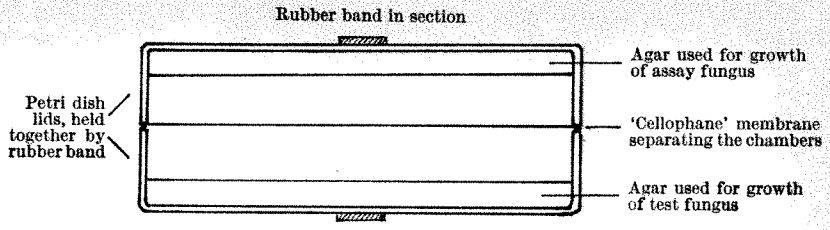

Fig. 1. Assembly used for the tests of effects of volatile metabolites

The survey has also examined the effects on zygospore production by *R. sexualis*, perithecial formation by *C. globosum*, and conidial formation by *A. niger* and *B. cinerea*. The effects on these very different reproductive processes varied, as was to be expected. Sixteen species significantly stimulated zygospore production, six species inhibited it significantly ($P = 0{\cdot}05$). Empirical observation indicated that two species (*Saccharomyces cerevisiae*, *Ceratocystis coerulescens*) inhibited perithecial production by *C. globosum* by more than 50 per cent, and three species (*Mucor plumbeus*, *Ceratocystis coerulescens* and *Fomes annosus*) stimulated zygospore production in *R. sexualis* but inhibited perithecial production in *C. globosum*. Eight species inhibited conidial production by *A. niger* and/or *B. cinerea* by more than 25 per cent.

This work has been carried out to give a preliminary indication of the likely frequency of occurrence of such metabolites, in expansion of earlier work in these laboratories[1] and by Lösel[2]. These published results are comparisons of means of observations of three replicate dishes in a single series of experiments. The main stimulatory and inhibitory effects have been confirmed by other experiments, but many of the differences are too small to justify discussion without further information. The general pattern, however, suggests that the occurrence may be widespread. No consistent relationship appeared in the range of effects on the measured characters of growth or of reproduction, and the distribution of activity showed no consistent relationship to any standard taxonomic system. The survey is being continued by investigations of the distribution of occurrence of such metabolites, of their effects on fungi and on green plants, and of their chemical structure and mode of action. Individual cases are being examined in detail; for example, active constituents of gas mixtures from cultures of *Saccharomyces cerevisiae* and of *Fomes annosus* have been identified by gas chromatography and biological tests of authentic pure compounds, and full descriptions are being published elsewhere (for example, ref. 3).

In vitro Development of Microfilariae of *Macacanema formosana* in Mosquito Cell Cultures

EARL[1] reported the maintenance of microfilariae in mixture 199 plus dog serum for 61 days. Sawyer and Weinstein[2] and Weinstein[3] reported development of the microfilariae of *Dirofilaria immitis* and *Wuchereria bancrofti*, respectively, to late first-stage ("sausage-form") larvae. This communication describes the *in vitro* development of

Figs. 1–5. Larval stages of *Macacanema formosana* showing development occurring in the presence of *Aedes aegypti* cells in culture. Fig. 1. Microfilaria from blood of monkey. Fig. 2. "Pre-sausage" form days 3–4 in culture. Fig. 3. "Sausage" stage day 5 in culture. Fig. 4. Second stage larva days 6–9 in culture. Fig. 5. Maximum stage reached in culture days 14–17

Macacanema formosana microfilariae through second- and possibly to third-stage larvae in the presence of *Aedes aegypti* cells in culture.

The *A. aegypti* cells are those of Grace[4] and have been maintained in serial culture for 3 years. They have been adapted by Suitor[5] to a growth medium consisting of 0·5 per cent *Philosamia cynthia* haemolymph, treated according to Grace[6], plus 10 per cent foetal bovine serum in Grace's[7] insect cell culture medium (GMA). The cells are cultured in 2-oz. glass or plastic screw-capped bottles at 28° C and have a generation time of approximately 42 h.

Microfilariae were obtained from the blood of a Taiwan monkey, *Macaca cyclopsis*. Five-ml. samples of blood containing 70–80 microfilariae/mm³ were drawn and placed in tubes containing heparin. Blood was held for 12–16 h at approximately 30° C until utilized. To separate microfilariae from the blood, 1 ml. samples were diluted in 10 ml. of 0·02 per cent saponin in Ringer's saline, *p*H 7·2. Complete lysis of the red cells occurred on incubation with intermittent shaking at 37° C for 15 min. The samples were washed by centrifuging at 1,500 r.p.m. for 4 min, discarding the supernates, and resuspending the pellets in 5 ml. of GMA. After the washing was repeated, samples were recentrifuged, as above, the supernates discarded, and the pellets resuspended in complete insect cell growth medium with or without *A. aegypti* cells. The growth media were not changed for the duration of the experiment.

Preliminary results indicated that development of the microfilariae failed to take place at 28° C, but did take place at 22° C. Since the insect cells in culture were able to multiply at 22° C, the following results were all obtained from experiments carried out at that temperature.

Development of the microfilariae was observed daily by direct-light and phase-contrast microscopy. Measurements were made with a calibrated ocular micrometer.

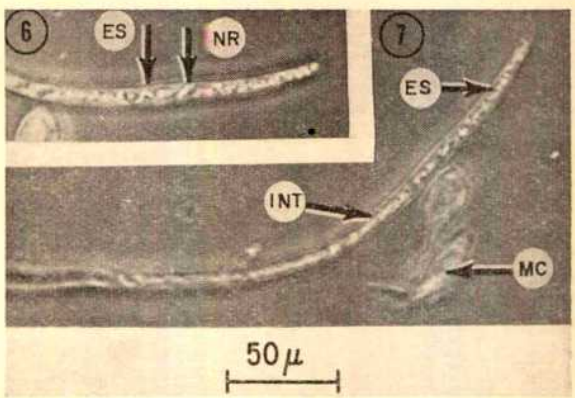
M. formosana microfilariae were 145–200μ by 3·0–3·8μ when isolated from the monkey blood (Fig. 1).

Microfilariae in complete insect cell medium without cells became sluggish within 2 days. They grew to 190–230μ by 6–7·5μ in approximately 6 days, after which many of them became vacuolated. Most of the microfilariae were dead by the seventh day.

In the insect cell medium with growing and multiplying cells microfilariae developed in the following manner:

On the third and fourth days (Fig. 2), the larvae became shorter and broader. Their movement was sluggish and their interior somewhat granular in appearance. A distinct tail was present.

On the fifth day (Fig. 3), the larvae reached the "sausage" stage. Movement during this period was minimal. "Sausage" stage larvae measured 120–128μ by approximately 9·6μ. Internal granulation was heavy.



On the sixth to ninth days (Fig. 4), the larvae grew rapidly in length and narrowed slightly. Ninth day larvae measured 230–270μ by 6–8μ. The interior of the larvae cleared partially and flexion movements increased during this time. Phase-contrast microscopy revealed internal development.

On the fourteenth to seventeenth days (Fig. 5), the larvae reached the maximum stage of development attained in this experiment. They measured 290–303μ by 6–9·6μ. These larvae were active and some made "probing" motions with the anterior end.

On the nineteenth day (Figs. 6 and 7), observations of larvae by phase-contrast microscopy showed the presence of a mouth, oesophagus, nerve ring, and intestine. The external cuticle of the larvae had separated but had not been shed. Larvae survived up to 33 days but developed no further. At the time of death, the larvae were heavily vacuolated and in a state of degeneration.

The development of internal organization (oesophagus, nerve ring, and intestine) in the *M. formosana* larvae after 5 days *in vitro* indicated that the larvae had reached second stage. However, no moult was observed. By the nineteenth day the mouth had opened to the exterior of the larvae and the oesophagus, intestine, and nerve ring had become more distinct. The larvae at this stage had moulted but still retained the external cuticle, and so the tail and the anal plug were still present. Although it cannot be stated that the "infective" stage was reached, definite development of second and possibly third stage larvae occurred. Attempts to test the infectivity of the larvae are planned.

No apparent reaction occurred between *M. formosana* larvae and the insect cells nor was multiplication of the cells impaired by the presence of the larvae. In several experiments where cell development was slowed during the initial days of incubation, apparently because of the lack of adequate amounts of growth-promoting substances in the medium, larval development was also retarded. This suggests that conditions necessary for cell develop-

Figs. 6–7. Phase-contrast microscopy of *M. formosana* larvae showing development attained in 19 days in the presence of *A. aegypti* cells in culture. *ES*, Oesophagus; *INT*, intestine; *NR*, nerve ring; *MC*, mosquito cell

ment are similar or identical to those necessary for development of the filarial larvae.

The life cycles of many parasites involve insects as intermediate hosts. An *in vitro* method for investigating this phase of development of a parasite, offering conditions closely approximating the environment in the insect, is highly desirable. Insect cells in culture may provide this method.

Types of Group Selection

THE terms group selection and intergroup selection[1,2] have been used in referring to a variety of phenomena including recently the evolution of behavioural social systems involved in population control[3,4]. Since the phenomenon of group selection promises to receive greater attention from students of evolution in the future, I feel that a clarification of terms at this time will help to prevent confusion. The "groups" under consideration may be quite different from each other and the action of natural selection on them will depend on the nature of the group.

At least two extreme types of group can be recognized: the family or lineage group and the population. Intermediate types occur, especially in species in which culture is important, but only the extreme types will be discussed here. The lineage group is a sub-group within a population, and is defined on the basis of kinship. A population in the ecological sense, although it may also have a common lineage, is generally defined from other populations spatially, irrespective of lineage. Theoretically the two concepts can overlap, but in practice this is not embarrassing. The term kin selection may be applied to lineage groups (following Smith[5] in part). The evolution of parental care, whether behavioural, morphological or physiological, may be attributed to kin selection.

The simplest lineage group is composed of one or more parents and their offspring. In the typical case the family group disperses before the first generation has reached maturity. In some social insects, a few species of birds, and in some other animals, the young remain with the parents and help to raise subsequent broods, as in some cases of "helpers at the nest"[6]. Among birds, in the Mexican jay (*Aphelocoma ultramarina*)[7], fairy wren (*Malurus cyaneus*)[8], Australian magpies (*Gymnorhina dorsalis*[9] and *G. tibicen*)[10], and some other species[11], territories may be defended by social groups larger than pairs, in which incipient communal behaviour may occur; but the most extreme development of this evolutionary potentiality in birds appears to be the situation found in certain anis (Crotophaginae) in which all phases of breeding may be communal[11]. In the latter cases, the extent to which inbreeding determines the genetic composition of successful groups is not known but deserves study.

Assuming lineage to be important in the latter cases, we can then recognize a continuum among various species in the importance and complexity of the family or lineage group and in the number of generations in which it may stay together as a unit. The existence of such a continuum is provided for in the expression "inclusive fitness" in Hamilton's[12] model for kin selection. It is possible at all positions on this continuum to recognize the existence of competition between lineage groups. This may be done whether the unit is a pair of titmice and their brood and the competition influences the evolution of clutch size[13] (simple extreme in Table 1) or if the unit is a flock of anis (*Crotophaga* spp.) and the competition determines the social organization and behaviour of the flock and species (complex extreme in Table 1). The critical point in all these cases is that the group is characterized (to varying degrees) by a common lineage, which is characteristically maintained by social bonds within a population and with no important ecogeographic isolation from other such groups. The evolution of the ability to form such social bonds is also provided for in Hamilton's[12] model.

Table 1. CHARACTERISTICS OF TWO TYPES OF GROUP SELECTION

	Kin selection		Interpopulation selection	
	Simple extreme	Complex extreme	Slight ecogeographic separation	Large ecogeographic separation
Lineage relationship	Simple family	Communal group	Irrelevant	Irrelevant
Duration of group	One generation	Indefinite	Indefinite	Indefinite
Gene exchange between groups	Unrestricted	Partially restricted by social behaviour	Partially restricted by geography	Nearly absent
Competition between groups	Sympatric	Sympatric	Allopatric	Allopatric

Smith[5] has referred to one extreme of this continuum as "group selection" and to the other extreme as "kin selection". In my opinion, because these cases may be recognized as lying along a continuum (provided for in Hamilton's[12] model) they should all be interpreted as representing one phenomenon, which may conveniently be called kin selection, or perhaps lineage selection. To use the term "group selection" for any of these cases is confusing, as Wynne-Edwards[3,4] has used "group selection" and "intergroup selection" in explicit reference to intraspecific interpopulation competition, which is quite a different phenomenon. In order to avoid confusion I propose the following definitions: selection between lineage groups within populations will be called kin selection; selection between spatially defined (allopatric) populations of a species will be called interpopulation selection (see Table 1).

Whether the term group selection will eventually prove useful as a generic term to include both kin selection and interpopulation selection remains to be seen. The differences between the two are significant. Kin selection depends on sympatric competition between lineage groups within a population and can be treated theoretically in a manner comparable to individual selection[12], since the basic time unit is most frequently the generation and the lineage groups are not prevented from interbreeding except partially in the complex cases, as in species with communal territories. Interpopulation selection depends primarily on allopatric competition; the basic time units are the time constants for extinction and colonization, and it may require a different type of mathematical expression, such as game theory[14].

This investigation was supported in part by a research grant from the National Institute of Mental Health, U.S. Public Health Service.

ENTOMOLOGY

Apolysis in Arthropod Moulting Cycles

FOR many years comparisons of moulting cycles in the Arthropoda have suffered from lack of a generally accepted terminology. The most ambiguous word, especially for Insecta, has been "moult", which has been used to denote two completely different events in the cycle.

The colloquial meaning of "moult", like that of "la mue" and "der Häutungsakt", has always been the visible shedding of the old shell, or exoskeleton, at ecdysis. When Snodgrass[1] wrote, "*Moulting*, with arthropods, is the separation of the old cuticle from the new cuticle formed beneath it; *ecdysis* is the emergence of the insect from the moulted skin", he was attempting to wrest the term moult away from its colloquial sense to apply it to an earlier, preparative event in the cycle: an event that had already been sharply distinguished from ecdysis in Crustacea by Drach[2] and in Insecta by Hinton[3].

Unfortunately, although the distinction between the two events was recognized to be of great physiological importance[4], and the term ecdysis was generally accepted for shell-shedding, the earlier event never received a specific name[5].

We now propose *apolysis* for the freeing of the epidermal cells from the old exoskeleton in any arthropod. It can be clearly seen in sections (Fig. 1), and is most like D_1 among the stages described by Drach[2] for Crustacea and "moulting" as defined by Snodgrass[1] for Insecta. Together with the secretion of at least some layers of the new cuticle and digestion of the old, apolysis is an essential preparation for the ecdysis which usually, though not necessarily, follows.

Apolysis is derived from the Greek 'απόλυσις, meaning "a freeing from" or, more particularly, "the loosing of a bandage"; it stands in contradistinction to ecdysis (ἔκδυσις), which means the actual "sloughing" of the skin. We are indebted to Prof. D. E. Eichholz for suggesting the new term.

Light-on and Light-off Effects on the Circadian Flight Activity in the Mosquito *Anopheles gambiae*

A PRELIMINARY investigation of the flight activity of female *Anopheles* (*Cellia*) *gambiae* Giles (Lagos strain) fed on sugar has been undertaken using a modification of the recording technique described by Jones[1]. Groups of five or ten recently emerged adults were placed in a 'Perspex' walled chamber (*c.* 1·5 l.). This was placed in a sound-proof box in a constant temperature room, maintained at 24°–26° C. The mosquitoes were supplied with a small quantity of 15 per cent glucose solution with a cotton wool "wick", which also served to maintain a relative humidity in the chamber of 65–85 per cent. Artificial lighting (150–200 lux) was used during both the rearing and experimental periods, and the light régimes were controlled with a simple time switch. Flight activity was recorded acoustically for periods of up to 1 week, and a direct record of the activity was made with a pen marker on a kymograph with a continuous paper roll attachment. A similar recording "channel", without mosquitoes, was used to record any unwanted acoustic or electronic interference which was loud enough to operate the pen markers.

Groups of females subjected to alternating periods of 12 h light and 12 h dark had periods of intense activity

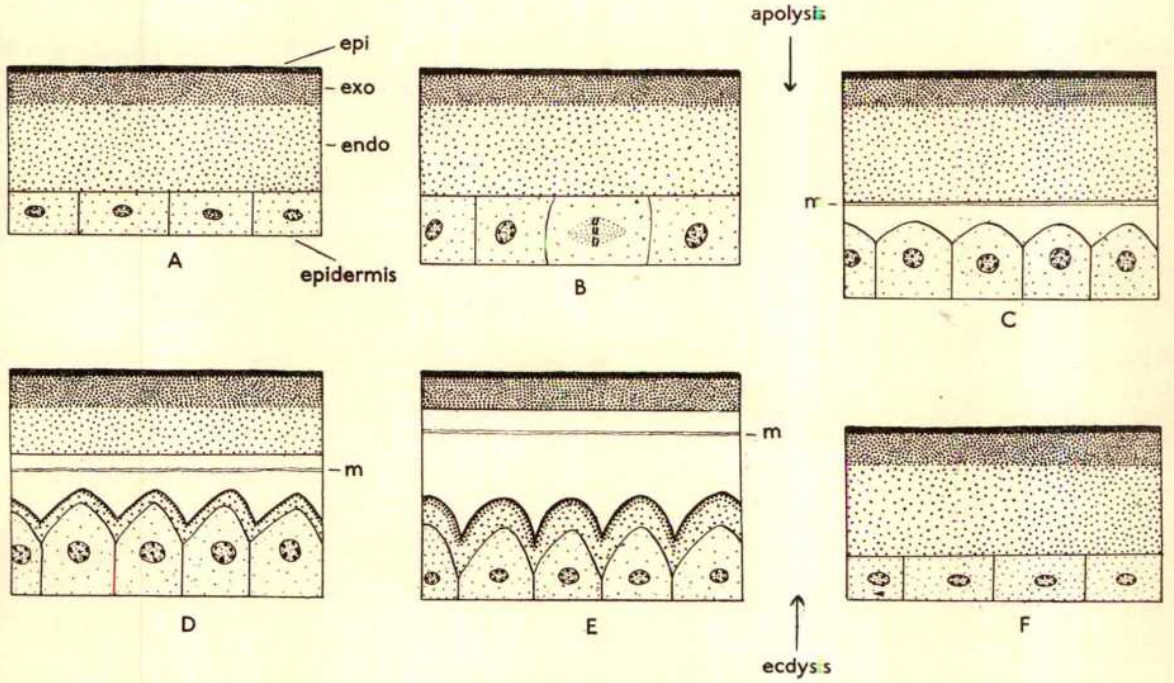

Fig. 1. (*A–F*) The successive changes in the form of the integument of an arthropod during and after the moulting cycle. *endo*, endocuticle; *epi*, epicuticle; *exo*, exocuticle; *m*, moulting membrane or ecdysial membrane

lasting about 20–30 min following both the light-on and the light-off signals. They were inactive during the remainder of the light period, but were usually active in "bursts" throughout the dark period. A 2 h dark period included in the first 9 h of a 12 h light period produced no response. If the light was switched off 3 h early, there was no immediate increase in activity, but the insects became active 1–2 h earlier than usual. If the light was switched off 6 h late, the onset of activity was delayed until the light was switched off.

There was no obvious cyclical pattern of activity in mosquitoes kept in constant light throughout their life, but cyclical activity with a period of about 23 h followed a change to constant dark. The active part of the cycle lasted about 12 h and the first period of activity started with the light-off signal. It is not clear from these findings whether the change resulted from the synchronization of the individual cycles which were previously out of phase, or whether the cycle was started by the change from light to dark.

The light-on and light-off responses differed in their respective latencies. Light-on activity usually started within a few seconds of the signal, whereas the onset of light-off activity was delayed usually for 1–5 min.

It would seem from these results that the pattern of flight activity is controlled by an endogenous rhythm similar to that which controls oviposition and sugar feeding in other mosquitoes[2–4]. The cycle has a free-running period in the dark of less than 24 h and light appears to have an inhibitory effect on activity. Thus, in alternating light and dark, activity is synchronized with the external régime by the delaying effect of light. Eyles and Bishop[5] have observed that egress of *Anopheles quadrimaculatus* from their resting places at sunset can be prevented by artificial illumination. The cycle is not immediately responsive to light-off signals given 3 h or more earlier than usual. The latency of the light-off response and the similarity with the results of other work[6] suggest that a hormonal mechanism is involved[7] and that light acts by inhibiting secretion. The speed of the light-on response suggests that it is mediated directly by the nervous system and may be a "startle" reaction to the sudden switching on of the light. Pre-adaptation of the insect to the dark may be an important constituent of this reaction.

We thank Mr. G. Davidson and Miss W. Wall, of the Ross Institute of Tropical Hygiene, for supplying the mosquito eggs.

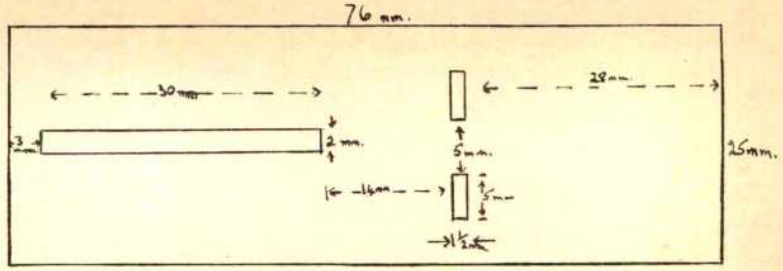

Fig. 1

HAEMATOLOGY

Haptoglobin Types in Dried Bloodstains

THE determination of haptoglobin types in dried bloodstains has until recently met with very limited success. The method for determining haptoglobin types using starch gel[1–4] is the most satisfactory technique available for serum samples. Direct transposition of this technique to bloodstains has been tried by many research workers[5–7] both in starch and acrylamide gels. The patterns obtained from stain material differ considerably from those shown by fresh serum samples. It is extremely difficult to interpret the results as they can be obscured by the excess haemoglobin present and it can only be done if the stain is very fresh (that is, not more than about 3 days old). The problem of excess haemoglobin can be overcome by subjecting the sample to a short preliminary electrophoresis in starch gel at *p*H 6·5 (tank buffer: 0·04 M disodium hydrogen phosphate adjusted to *p*H 6·5 with *ortho*-phosphoric acid; gel buffer: 20 ml. tank buffer diluted to 150 ml.). At this *p*H, haemoglobin moves towards the cathode while the haptoglobin/haemoglobin complex moves towards the anode. After 30 min electrophoresis at 6 V/cm, a block of gel about 1 cm² is removed on the anodic side of the origin and inserted into a gel at *p*H 8·6 with a buffer system according to Poulik[4]. However, we required a method which was accurate and would allow the determination of haptoglobin types in stains at least one month old. These conditions have been met by using an immuno-electrophoresis method.

Immuno-electrophoresis was carried out using the buffer system described by Hirschfeld for *Gc* groups[8] using 1 per cent 'Ionagar'. (Tank buffer, 1·38 g barbituric acid, 8·7 g sodium barbitone, 0·384 g calcium lactate, 2 l. water. Gel buffer, 0·553 g barbituric acid, 3·503 g sodium barbiturate, 0·512 g calcium lactate, 1 l. water *p*H 8·6.)

The gels were cut into the pattern shown in Fig. 1.

It was found that antigen slots give better definition of precipitate arcs than the more usual circular wells. It also enabled sufficient antigen to be inserted into the gel while keeping the origin narrow. Enough stain material to fill the antigen slot was soaked in a minimum of gel buffer for 30 min–1 h before inserting it into the gel. Electrophoresis was carried out at 6 V/cm for 4·5–5 h at 4° C. Anti-haptoglobin serum was used to fill the central trough and diffusion was allowed to proceed for 24–36 h at 4° C. Most batches of antisera were diluted 1 : 4 with gel buffer. The haptoglobin types could be determined by the differing position, length and shape of the precipitate arcs, as shown in Fig. 2.

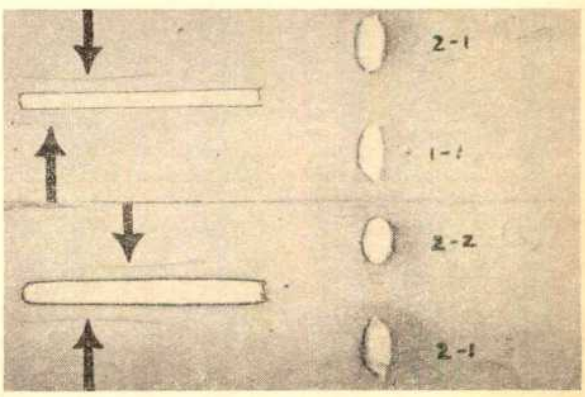

Fig. 2

The accurate interpretation of these arcs takes considerable practice. The most important parameter is the position of the peak of the arc. These are indicated by arrows in Fig. 2. The interpretation of the length and shape of the arc will follow with practice if attention is centred on the peak of the arc. In many cases it is possible to read the precipitate arcs in the wet gel. We have, however, found it better to reserve final judgment until saline washing (24 h), drying and staining the gel in amido black are completed. Weak precipitates can be seen clearly after this procedure. As the position of the arcs shifts progressively towards the cathode with age of the stain components, stains of a similar age and of known haptoglobin types should be run as controls at the same time as the suspect material. This should be done on each run as slight variation of movement can occur from one run to the next depending on the operator.

Stains up to 3 months old have been correctly typed. The type of cloth which forms the substrate of the stains seems to have only a quantitative effect; more material is required (in area of cloth) if the substrate is cotton than if it is wool. The intensity of the bloodstaining also has considerable bearing on this, of course. Experience is required in estimating the correct amount of material to use.

Many hundreds of these determinations have now been made in this Laboratory both on test and case material and we are satisfied that this is a method which can be used in the routine examination of bloodstains in forensic laboratories.

All this work has been performed with Shandon immunoelectrophoresis equipment and Dutch Red Cross antisera.

After this work was completed a report by Hallermann, Kiwi and Sturner[9] came to our notice which describes work on similar lines. Hallermann *et al.* suggested the use of a modified gel buffer containing glycerine. Its composition is: Solution *A*, 7·505 g glycine, 3·85 g sodium chloride, 1 l. water. Solution *B*, 0·1 M sodium hydroxide. 62·5 ml. of solution *A* are mixed with 37·5 ml. of solution *B* giving a buffer of *p*H 10·0, $\mu = 0{\cdot}15$. This is diluted to $\mu = 0{\cdot}05$ and mixed with an equal volume of barbituric lactate gel buffer mentioned earlier. The tank buffer remains the same as before. We have tried this and find that on some occasions the separation is marginally better, while on other occasions no difference can be detected.

Morphological Variations in the Eosinophil Granule revealed by Cytochemical Methods

MORPHOLOGICAL variations in the human eosinophil granule under electron microscopic examination have been recently recorded[1]. Furthermore, other variations in the eosinophil granule have been described before[1]. In fact, it seems probable that there are two or more different populations of granules.

This concept is substantiated by my own findings[2,3]. The regularity and morphological features of sudanophilia and peroxidase activity in human peripheral blood eosinophils were studied in an attempt to provide normal data for succeeding investigations. Material was obtained from 104 normal adults of both sexes. The reactions of eosinophils have been observed using Sheehan and Storey's[4] and Washburn's[5] methods, for sudanophilia and peroxidase activity, respectively.

Both sudanophilia and peroxidase activity were similar in appearance and intensity in all the granules of 83 per cent (82·8 per cent, sudanophilia, 83·1 per cent, peroxidase activity) of the eosinophils. However, in 17 per cent the positive granules showed wide variations in number, size, shape, colour, and distribution. In many cases several varieties of granules occurred in one eosinophil.

Thus, sudanophilia parallels peroxidase activity in human peripheral blood eosinophils and both may exhibit different features in the granules of one eosinophil.

Sufficient material now exists to support a working hypothesis on identification and characterization of distinct eosinophil granules with evolutionary and functional criteria.

Coagulant Activity of Tiger Snake (*Notechis scutatus scutatus*) Venom

TIGER snake venom has the ability to clot blood. Holden[1] and Blömback[2] have presented evidence that prothrombin, Factor V and calcium ions are required for the venom to convert fibrinogen to fibrin. We have studied the action of this venom on several purified clotting factors. As the crude venom was used in these experiments, the results obtained may arise from more than one active constituent present in the venom.

In preliminary experiments with plasma systems, it was confirmed that the venom exerts its optimal coagulant activity only in the presence of prothrombin, Factor V, a divalent metal (calcium, barium, strontium or manganese), and a phospholipid emulsion which is able to increase the rate of activation of prothrombin. The venom had very little coagulant activity on purified human fibrinogen (Kabi Pharmaceuticals, Ltd.). Furthermore, the venom neither activated nor destroyed Factor X. When purified bovine Factor X (ref. 3), or Factor X in human serum, was incubated at 37° C with tiger snake venom (Koch-Light Laboratories, Ltd.), phospholipid and calcium ions, no activated Factor X was produced; if, however, after 30 min Russell's viper venom was added, it converted all the Factor X to the active form (X*a*). This is interesting in itself, as no other venom has yet been shown to be capable of activating prothrombin and incapable of activating Factor X (refs. 4 and 5).

Blömback[2] has proposed that the coagulant substance of tiger snake venom acts on Factor V, and as a result Factor V acquires the ability to activate prothrombin. In his experiments, incubation of a partially purified Factor V preparation with the venom produced a prothrombin converting activity which increased with time. However, we have repeated these experiments with pure bovine Factor V (ref. 6), and have found that incubation of Factor V with the venom, with or without phospholipid ('Inosithin') and calcium ions, produced no progressive increase in coagulant activity, but rather a gradual inactivation occurred.

The rate of activation of purified bovine prothrombin by the venom in purified systems was studied, with conditions as described elsewhere[7]. The effect of adding Factor V, phospholipid (phosphatidic acid/phosphatidylcholine, 1 : 1) and calcium ions to prothrombin and the

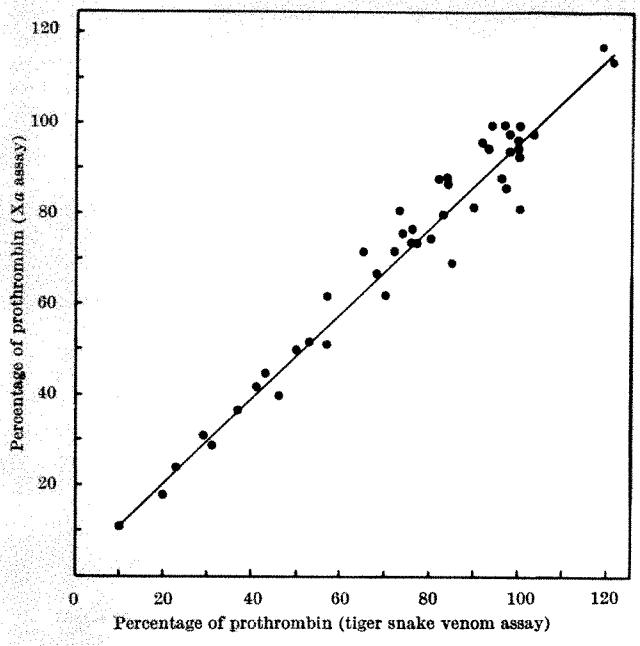

Fig. 1. Correlation between tiger snake venom assay and Xa assay of prothrombin. Regression line of y on x

venom in various combinations is shown in Table 1. The results are expressed as relative rates of prothrombin activation, and are compared with those obtained with activated Factor X (Xa). It can be seen that the venom and Xa have very similar properties; however, in the absence of calcium, Factor V increases the rate of prothrombin activation by the venom, but not by Xa.

Table 1. A COMPARISON OF THE RELATIVE RATES OF PROTHROMBIN ACTIVATION BY TIGER SNAKE VENOM (TSV) AND Xa IN THE PRESENCE OF FACTOR V, PHOSPHOLIPID AND CALCIUM IONS IN VARIOUS COMBINATIONS

Mixtures	Relative rates With TSV	With Xa
Prothrombin	0·033	0·36
Prothrombin + phospholipid	< 0·10	< 0·27
Prothrombin + Ca	1·0	1·0
Prothrombin + V + phospholipid	4·5	—
Prothrombin + V	22·3	0·87
Prothrombin + phospholipid + Ca	27·0	50·1
Prothrombin + V + Ca	145·8	311·0
Prothrombin + V + phospholipid + Ca	4,687·5	1,610·0

It is known that Xa is adsorbed on to some phospholipids in the presence of a divalent metal, and this is also true for the venom coagulant activity. As shown in Table 2, Xa and the venom activity are adsorbed on to phosphatidic acid/phosphatidylcholine (1 : 1) in the presence of calcium, barium or strontium ions, but there is little adsorption in the presence of magnesium. Moreover, both the venom activity and Xa show little ability to form a complex with an emulsion of pure phosphatidylcholine, which suggests that a negative surface charge on the phospholipid micelles is required for the formation of such complexes[6].

Table 2. ADSORPTION OF TIGER SNAKE VENOM (TSV) AND Xa ON TO EMULSIONS OF PHOSPHATIDIC ACID/PHOSPHATIDYLCHOLINE (PA/PC) AND PHOSPHATIDYLCHOLINE (PC) IN THE PRESENCE OF DIVALENT METALS

Phospholipid	Divalent metal	Activity adsorbed (per cent) TSV	Xa
PA/PC	None	< 3	0·02
PA/PC	Ba	105	63
PA/PC	Sr	29	13
PA/PC	Mg	6	0·16
PA/PC	Ca	100	100
PC	**Ca**	**7**	**8·7**

In view of these findings, we felt that the venom could be used in a one stage assay of prothrombin. Various modifications of the original one-stage prothrombin assay of Quick[8] have already been introduced in order to increase the specificity of the test. Spaet and Cintron[9] have devised a prothrombin assay in which Xa is added and converts prothrombin to thrombin in the presence of a high concentration of Factor V, fibrinogen, phospholipid and calcium ions. However, the test requires purified Xa, and it occurred to us that a similar assay could be designed in which tiger snake venom would be used instead of Xa.

0·1 ml. of the citrated plasma to be tested, diluted 1/10 in buffered saline (*p*H 7·5), was added at 37° C to 0·1 ml. of oxalated barium sulphate absorbed bovine plasma. Then 0·1 ml. of 0·025 M calcium chloride was added, followed quickly by 0·1 ml. of a mixture of 'Inosithin' (Associated Concentrates, Ltd.) 1·4 mg/ml. and tiger snake venom (60–120 μg/ml.) or Xa. Serial dilutions of normal citrated human plasma in buffered saline between 1/10 (100 per cent) and 1/1,000 (1 per cent) were assayed and a log dose was plotted against log clotting time. In a typical assay with the venom, the 1/10 (100 per cent) and 1/100 (10 per cent) dilutions of the normal plasma gave clotting times of 11 and 31 sec respectively, and the assay gave a blank clotting time of 80–90 sec. A significant correlation was obtained between the results given by the venom assay and those given by the assay with Xa (Fig. 1) in a study of forty-five different plasmas (correlation coefficient: 0·96).

A comparison was also made between the venom assay and the two-stage prothrombin assay[10]. Plasma samples sent to the laboratory for a routine two-stage prothrombin test which gave a "prothrombin" estimation of less than 50 per cent were also assayed by the venom test. As shown in Fig. 2, there is a considerable discrepancy between the estimations given by the two assays.

The essence of the two-stage test is such that an abnormal level of plasma antithrombin activity might affect the result of the assay. Therefore, each plasma included in this study was assayed for its thrombin inhibitor(s) activity[10]. The plasmas which have a thrombin inhibitor(s) activity higher or lower than 115 per cent of normal have been indicated in Fig. 2, in order to illustrate the major source of discrepancy between the assays which is associated with a rise of plasma thrombin inhibitor(s), as well as the frequency of occurrence of these abnormal levels in the group studied.

The most likely explanation of this discrepancy is that the two-stage test gives unduly low prothrombin estimations when there is a high titre of plasma thrombin inhibitor(s). In cases of obstructive jaundice, there is often a rise in antithrombin III (ref. 11), and this may occur with or without vitamin K deficiency. Therefore,

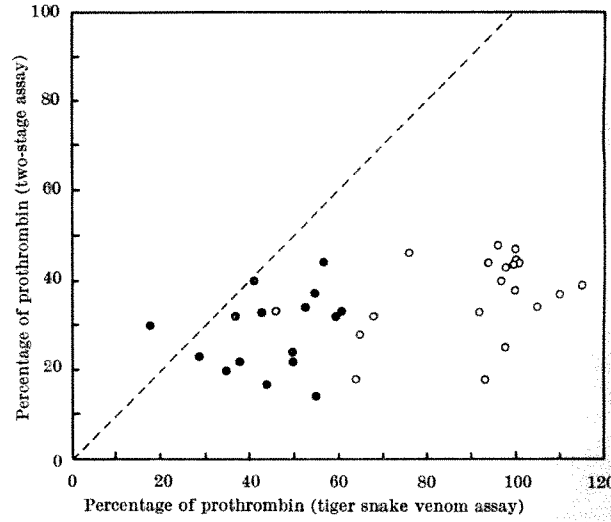

Fig. 2. Correlation between the two-stage prothrombin test and the prothrombin assay with tiger snake venom. ○, Thrombin inhibitor ⩾ 115 per cent; ●, thrombin inhibitor < 115 per cent

the inability to correct a low two-stage test by the parenteral administration of vitamin K might not necessarily indicate a severe parenchymal liver lesion.

IMMUNOLOGY

Immunofluorescent Staining of Globule Leucocytes in the Colon of the Sheep

THE nature and fate of the globule leucocyte are of particular interest in relation to the immune mechanisms of the gut since it has been shown to increase during helminth infection[1] and appears to have certain affinities to plasma cells and Russell's body cells which have been shown to contain antibody[2].

Four previously worm-free sheep were experimentally infected with 1,500 infective larvae of *Oesophagostomum columbianum* and killed after ten weeks of infection. Tissue samples were taken from the colon and caecum of each animal and fixed in Helly's and Carnoy's fluids and cold acetone, embedded in paraffin wax and sectioned at 4μ according to the method of Culling[3].

Fluorescein isothiocyanate-conjugated rabbit anti-guinea-pig and rabbit anti-sheep globulin were obtained from Difco, Detroit. Rabbit anti-human serum was prepared according to the technique of Kabat and Mayer[4] and conjugated together with normal rabbit and human sera using fluorescein isothiocyanate following the technique of McDevitt *et al.*[5].

Sections of sheep colon were stained using rabbit anti-sheep globulin to detect globulins within cells; the rabbit anti-guinea-pig globulin and anti-human serum were used to test the specificity of this reaction. Further controls were made using conjugated normal rabbit and sheep globulin and unconjugated rabbit and sheep serum to test for non-specific attachment and for fluorescence of the serum proteins themselves. Phosphate buffered saline controls were used to test for fluorescence of the unstained sections. A slide of the aqueous mountant alone was also tested for fluorescence.

All the histological sections were first taken to water in the usual way and rinsed in phosphate-buffered saline, *p*H 7·2, for 15 min. Each slide was then flooded with the test fluorescent stain or control solution and left for 1 h. The slides were all rinsed using phosphate-buffered saline twice for 15 min and once for 1 h; these were then mounted using aqueous mountant and scanned.

All microscopy was done using a Leitz 'Ortholux' microscope with transmitted ultra-violet and white light with a dark ground condenser D1.20 A and an Fl. Oel. 95/1.32 objective with an Oel. 100/Fl. Oel. 95 × D1.20 stop inserted. Photographs of all the sections were taken with a Leitz 'Orthomat' photographic attachment using Ilford Pan *F* 50 *ASA* film.

Only in the sections stained with conjugated rabbit anti-sheep globulin was any fluorescent staining noted. All the globules in the globule leucocytes fluoresced (Fig. 1) and the plasma cells showed a similar fluorescence. In many of the plasma cells large fluorescent globules were shown which were of a similar size to those in the globule leucocytes. No fluorescence above a faint non-specific level was noted on any of the control sections (Fig. 2).

Fig. 1. Globule leucocyte stained with fluorescein isothiocyanate-labelled rabbit anti-sheep serum

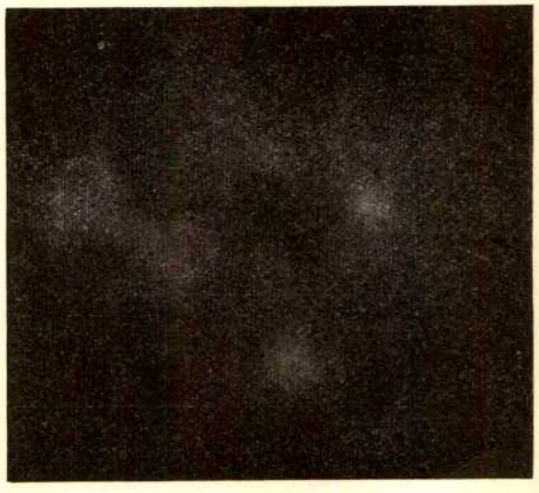

Fig. 2. Globule leucocyte from a control slide

It can thus be concluded that the cytoplasm of the globule leucocyte contains condensations of globulin. The similarities between the staining, the nuclear structure and the presence of globules of similar size and shape in the plasma cells and the globule leucocyte suggest that there is some relationship between these cells.

PATHOLOGY

Susceptibility of Old World Monkeys to Yaba Virus

Bearcroft and Jamieson[1] reported an outbreak of a tumour epidemic in the laboratories of the West African Council for Medical Research in Yaba, Nigeria, among imported rhesus monkeys. Andrewes *et al.*[2,3] showed that this epidemic resulted from a virus of the pox group. Sproul *et al.*[4] classified the tumour as a histiocytoma. Earlier, we reported[5] that Asiatic monkeys (*Macaca mulatta*, *Macaca irus* and *Macaca speciosa*) are susceptible to the virus, and that a tumour developed, following accidental inoculation, in a laboratory worker as well as in five cancer patients. By contrast, African monkeys (*Cercopithecus aethiops*, *Cercopithecus aethiops pygerythrus*, *Cercopithecus mona* and *Cercocebus fuliginosus*) imported from east and west equatorial Africa are resistant. The hypothesis was advanced that this virus may be endemic in certain areas of Africa and that most African monkeys develop immunity at an early age.

As one approach to investigating this hypothesis, a number of young monkeys from African species born in our colony or in zoos in the United States were inoculated subcutaneously with dilution series of Yaba virus suspensions. Animals from the same species imported from Africa were also inoculated. Each virus suspension used in this investigation was also inoculated into at least two *Macaca speciosa* imported from Asia. "Takes" were defined as production of lesions at least 0·5 cm in diameter which persisted for at least 3 weeks, which showed characteristic histological features[4,5] and, when homogenized and injected subcutaneously into *Macaca mulatta*, produced similar lesions.

Table 1

Species	Takes/No. inoculated		
	African import	U.S. born	Asiatic import
Sooty mangabey (*Cercocebus fuliginosus*)	0/4	2/2	
Vervet monkey (*Cercopithecus aethiops pygerythrus*)	0/4	1/1	
Anubis baboon (*Papio anubis*)	0/3	1/1	
Patas monkey (*Erythrocebus patas*)	0/1	1/1	
Stumptail macaque (*Macaca speciosa*)		1/1	10/10

Table 1 summarizes the results. All African monkeys born in the United States and all Asiatic monkeys developed tumours with 10^{-2}–10^{-4} as the maximal effective dilutions of the virus; none of the imported African monkeys showed any reactions. These results seem to support the hypothesis that African monkeys acquire immunity to Yaba virus in their natural habitat; resistance does not seem to be species specific. It must be kept in mind, however, that in this investigation most of the monkeys born in the United States were young (several months beyond weaning), while most of the imported monkeys appeared somewhat older, although their exact age was unknown. Another weakness of this experiment is the small number of African monkeys born in the United States which were available for investigation.

This work was supported by grants from the American Cancer Society, the National Cancer Institute, National Institutes of Health, U.S. Public Health Service, and the United Health Foundation of Western N.Y.

Electrophoretic Heterogeneity of Erythrocyte and Leucocyte Glucose-6-phosphate Dehydrogenase in Italians from Various Ethnic Groups

PREVIOUS investigations of drug-induced and fava bean-induced haemolytic anaemia in subjects with a deficiency of glucose-6-phosphate dehydrogenase (G-6-PD) have demonstrated that they are similar both in their clinical characteristics and in the mechanism of genetic transmission of the enzyme defect. Nevertheless, a considerable amount of evidence has accumulated to indicate that this enzyme defect reflects heterogeneous genetic mechanisms in various ethnic groups. It has been demonstrated that the enzyme deficiency may be complete or intermediate, that it may affect erythrocytes alone or involve other tissues[1–3], and that the enzyme protein may differ in its characteristics in cells from subjects of different ethnic groups[3–7]—including its electrophoretic behaviour.

These investigations were almost exclusively undertaken with the erythrocyte enzyme. It is well known that in affected Caucasian male subjects the leucocyte G-6-PD is deficient while it is normal, or almost normal, in Negro subjects of both sexes[3,8]. The enzyme activity is very low (rarely more than 2 per cent of the controls and thus not suitable for assay) in the erythrocytes from sensitive Sardinian subjects which we have extensively studied[6,9–11], and usually in sensitive Caucasian subjects[3,8,12]. Accordingly the leucocyte enzyme is especially suitable for an investigation of the properties of the mutant enzyme in this ethnic group.

In this investigation, a careful study has been made of the properties of leucocyte G-6-PD and a comparison has been made with the erythrocyte enzyme of sensitive subjects from several ethnic groups. The present research is concerned with investigations of a group of twenty-nine subjects from three Sardinian families, from a Sicilian family and from a north Italian family. Our results indicate alterations in electrophoretic patterns of leucocyte G-6-PD from the sensitive subjects, and heterogeneity in the characteristics of the enzyme among the families from Sardinia, Sicily and north Italy.

The families studied were identified when the propositus was admitted to hospital with a haemolytic crisis. The propositi are: case Nos. 5, 11, 12 and 20 for a fava bean-induced haemolytic episode; case No. 24 for a rifocin-induced haemolytic episode; case No. 29 for a pyramidone-induced haemolytic crisis.

Crude samples of the enzymes were prepared as previously described[13]. The modification of the Tsao technique[14] for descending starch-gel electrophoresis which we used has already been described[15], as have the procedures for the G-6-PD and 6-phosphogluconate dehydrogenase (6-PGD) assays used to determine the protein and haemoglobin content[13].

Fig. 1 shows an example of the electrophoretic migration of erythrocyte (case Nos. 9 and 16) and of the leucocyte (case Nos. 3, 12 and 24) G-6-PD from normal and mutant subjects. Two bands were frequently present in the preparations of the leucocyte enzyme, both for male and female normal and mutant subjects. The faster moving band is more intensively stained and results from G-6-PD activity, while the slower one is much less apparent and can be attributed to 6-P-GD. We were able to show that this slower band was in fact 6-P-GD and not a G-6-PD isoenzyme in the following ways: (1) The colour was developed in the usual manner, the slice was then carefully washed and the blue tetrazole stain developed in the presence of 6-phosphogluconate as substrate. The new stain appeared in the same band as the slower component and gave added intensity to the latter. (2) When two symmetrical gel slices were separately stained for G-6-PD and for 6-P-GD, there was a perfect correspondence between the 6-P-GD band and the slower band which appeared in the G-6-PD slice.

The electrophoretic behaviour and activity of the erythrocyte and leucocyte enzymes from twenty-nine subjects are given in Table 1. The results can be summarized as follows:

(1) The subjects from the three Sardinian families showed a strikingly similar behaviour in the hemizygote subjects (case Nos. 3, 4, 5, 6, 7, 11, 12 and 20) and in the homozygotes (case No. 2), with the complete erythrocyte defect and with leucocyte G-6-PD markedly diminished (the activity was about 50 per cent of that of the controls) and altered in its electrophoretic behaviour (the rate of flow was slower). In the female heterozygotes (case Nos. 9, 10, 16 and 19), the erythrocyte G-6-PD showed a lowered activity and a slower electrophoretic mobility, while the leucocyte enzyme was normal. Case No. 17 could be classified as an abnormal homozygote and was of special interest because of its features: it exhibited a very low, but still detectable, level of activity and we were able to demonstrate (by the activity level and the electrophoretic run) the defect both in the red and in the white blood cells. Our results clearly indicate that in the Sardinian mutant subjects the leucocyte enzyme defect has an unusual genetic trait and this was also the case for the erythrocyte enzyme.

(2) The north Italian family can be considered an interesting variant. As a matter of fact, both in the male (case No. 24) and in the female mutants (case Nos. 23 and 26) the erythrocyte enzyme shows an intermediate activity and normal electrophoretic behaviour. The leucocyte enzyme has a normal activity but slower electrophoretic mobility. It is also different from what has been described for the Barbieri family[5], and for some intermediate Greek[12], German and Irish[8] mutant subjects.

(3) The only alteration which we could detect in the Sicilian family was the markedly slower electrophoretic migration of the leucocyte G-6-PD. It is apparent from the anamnesis that both the mother and a son had had haemolytic episodes following the ingestion of peas and drugs.

* A unit of activity of G-6-PD is defined as the amount of enzyme required to give an increase in optical density at 340 mμ of 1·0 per min. The erythrocyte specific activity is referred to 1 g of haemoglobin and that for leucocytes to 1 g of protein.

† The electrophoretic mobility of the enzyme is expressed as a percentage of the mobility of the controls. The values related to case Nos. 23, 24 and 26 are the average of three determinations carried out at various times.

‡ Not detected.

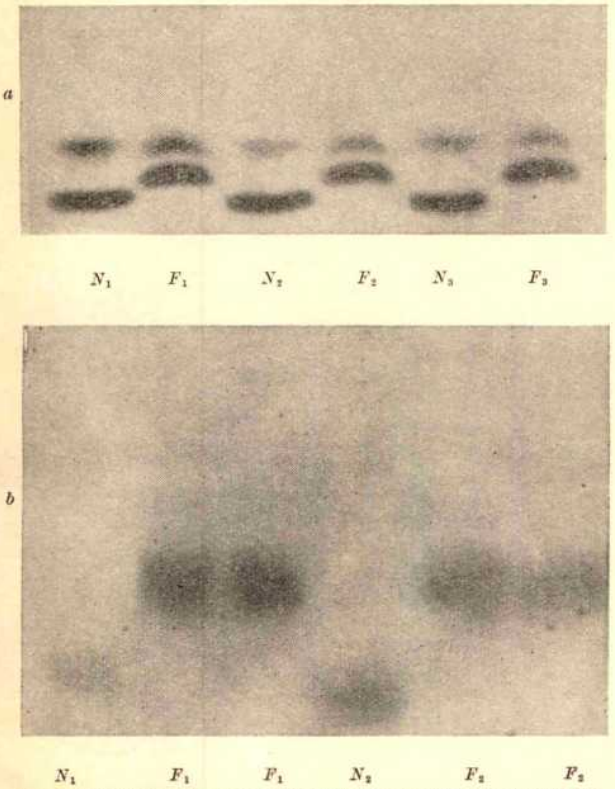

Fig. 1. Electrophoretic mobility of erythrocytes and leucocytes G-6-PD in starch gel of normal and mutant subjects. *a*, The leucocyte enzyme: F_1, F_3 and F_3 refer to case Nos. 3, 12 and 24; *b*, erythrocyte enzyme: F_1 and F_2 refer to case Nos. 9 and 16. Channels indicated as N refer to control enzymes

These results suggest a heterogeneity of G-6-PD deficiency in various Mediterranean ethnic groups and offer some evidence for a definite alteration in the electrophoretic pattern of the leucocyte G-6-PD from sensitive subjects.

This study was supported by a grant from the U.S. National Institutes of Health.

Uptake of Iodine-131-labelled Atabrine by Ehrlich Ascites Tumour and by Sarcoma S-180 *BALB*

ACKERMAN[1,2] reported a selective incorporation of iodine-131-labelled atabrine by lung and subcutaneous Novikoff hepatoma and Walker carcinosarcoma-256 tumours. In order to provide more information concerning the usefulness of this labelled compound for the localization and diagnosis of malignant tumours, we investigated its uptake by Ehrlich ascites tumours and sarcoma *S*-180 *BALB*.

A group of *BALB* mice was inoculated with Ehrlich ascites tumour cells. Eight days later they were injected subcutaneously with 10 μc. of iodine-131-labelled atabrine (specific activity, 0·12 mc./mg)[3]. Groups consisting of five animals each were killed 1, 2 and 5 days after the injection. The intraperitoneal exudate was immediately withdrawn with a syringe and centrifuged at 3,000 r.p.m. for 15 min. Both centrifugates and supernatants were counted for radioactivity with a scintillation counter; in addition, the radioactivity in the liver, spleen and leg muscles was measured. A control group of healthy animals injected with the same dose of iodine-131-labelled atabrine was killed at the same time intervals; the intraperitoneal cavity was washed with distilled water and the water counted for radioactivity under the same conditions. As in the experimental group, the radioactivity retained by the liver, spleen and muscles of control animals was measured. Table 1 gives values corresponding to the specific activities found (c.p.m./g tissue).

A similar injection test was performed on a group of five *BALB* mice with sarcoma *S*-180 *BALB*. These tumours were produced by inoculating tumour-cells 20 days beforehand. The animals were killed 5 days after the intraperitoneal injection of the iodine-131-labelled atabrine. The subcutaneous tumours were excised and also the adjacent and abdominal muscles. The radioactivity was counted in each case (Table 1).

* c.p.m./ml.
† Standard deviation.

The experimental results revealed that the activity incorporated by the Ehrlich ascites tumour cells remained almost unchanged throughout the experiment; the control group showed no significant activity. The pattern of uptake and elimination by the liver and spleen was similar in both groups and the observed variations between them could be related to the influence of increased fluid content in the body of tumour-bearing animals. The most significant finding was the retention of iodine-131-labelled atabrine by the tumour cells, whereas in the other tissues of normal and ascitic animals the radioactivity decreases considerably. The liver, however, is the exception to the rule. This organ has previously been shown to be responsible for the elimination of this labelled compound through the gastrointestinal tract[3].

The sarcoma *S*-180 *BALB* showed slightly greater activity than the surrounding leg muscles.

These findings seem to corroborate the preferential uptake of certain aminoacridine compounds by the tumour tissue observed by Ackerman.

Interaction of Poly-2-vinylpyridine-1-oxide with Silicic Acid

THE ability of poly-2-vinylpyridine-1-oxide (P204) to prevent the pathogenic action of quartz particles in the lungs of experimental animals and the cytotoxic effect in cell cultures has been repeatedly demonstrated[1]. Its mode of action is uncertain. Apparently it does not act by coating the particles because it is more effective if the P204 is added to the culture or is injected intraperitoneally into the animal than if the dust is pre-treated with it. Weiss and Harvey[2] suggested that P204 may be oxidized in the tissues to poly-2-vinyl-6-hydroxypyridine-1-oxide which might interact with silicic acid formed by dissolution of the quartz. They demonstrated that stable cationic silicon complexes are formed between 2-hydroxypyridine-1-oxide and *ortho*silicic acid. We have found that interaction occurs between poly-2-vinylpyridine-1-oxide itself and silicic acid by hydrogen bond formation.

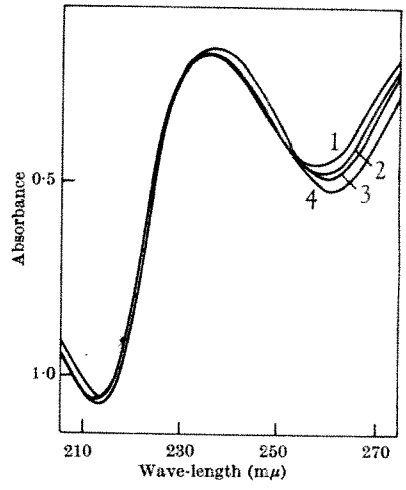

Fig. 1

Poly-2-vinylpyridine-1-oxide in chloroform has an electronic absorption spectrum with a peak at λ_{max} = 272·5 mμ (see Fig. 1 and Table 1). In ethanol this peak is shifted to λ_{max} = 268·5 mμ and there is an additional peak at λ_{max} = 220 mμ, the latter being obliterated by chloroform. In water P204 gives peaks at 213 mμ and 260·5 mμ. These values indicate that polyvinylpyridine oxide forms hydrogen bonds with water and with ethanol. When the oxide is dissolved in freshly prepared 0·01 M aqueous silicic acid, the peaks are at 213 mμ and 259 mμ. The shift of the longer wavelength peak indicates that the oxide hydrogen bonds more strongly with silicic acid than with

Table 1. ABSORPTION SPECTRA OF POLY-2-VINYLPYRIDINE-1-OXIDE

Solvent	λ_{max} (mμ)	ε_{max}
Chloroform	272·5	6,636
Ethyl alcohol	268·5	6,486
Water	260·5	5,300
Aqueous silicic acid*	259·0	4,550

* When the solution stood for 24 h, λ_{max} shifted to 257·0 (ε_{max} = 4,500).

water. If this solution is allowed to stand for 24 h, the peak shifts further to 257 mμ. It is probable that this does not arise from polymerization of the silicic acid, but from unfolding of the polymer chains which makes more groups available. If the silicic acid is allowed to stand for 24 h before admixture with the polymer, the absorption peak is at 259·5 mμ.

It would seem that the action of polyvinylpyridine oxide in preventing the pathogenic action of quartz may result from the direct action of the polymer itself, without its previous oxidation, in mopping up *ortho*silicic acid as it is formed in macrophages. These observations support the view that the pathological changes in silicosis are initiated by *ortho*silicic acid resulting from the dissolution of silica particles in the cytoplasm of phagocytes.

The P204 was prepared by oxidizing polyvinylpyridine (Midland Tar Co., Ltd.) with hydrogen peroxide in acetic acid. This report results from research sponsored by the Asbestosis Research Council.

Some Effects of Certain Naturally Occurring Oestrogens on the Anterior Pituitary Glands of Rats

THE earliest investigations of the effects of oestrogens on the cytology of the anterior pituitary gland were made using oestrone[1–3] which was first isolated in crystalline form in 1929. Diethylstilboestrol, a synthetic substance with oestrogenic activity, has been used in most of the more recent work[4,5]. In this communication the cytological effects of chronic administration of the naturally occurring oestrogens—oestrone, equilenin, 16-epioestriol and oestriol—on the anterior pituitary gland of ovariectomized rats are compared: the action of the last three has not been previously investigated. Measurements of the DNA content of individual nuclei from pituitary glands of rats treated with the oestrogens and of controls were made using Feulgen micro-spectrophotometry.

Sixty-three female Sprague–Dawley rats were divided into seven equal groups. Six groups were ovariectomized at 90–100 days of age: one group was maintained as ovariectomized controls, a second group was injected subcutaneously with 1 ml. corn oil daily, and the third, fourth, fifth and sixth groups were given daily 0·05 mg of oestrone, equilenin, 16-epioestriol and oestriol respectively, each dissolved in 1 ml. of corn oil. The seventh group was maintained as intact controls. The rats from groups 3, 4, 5 and 6 were killed at 3, 6 and 14 months after starting oestrogen treatment, together with the appropriate controls. The pituitary glands and the uteri were weighed. Each pituitary was cut sagittally with a razor blade, just beyond the lateral edge of the posterior lobe. Prints of nuclei were taken on coverslips from the cut surface: these were freeze substituted, hydrated and then stained under rigorously controlled conditions with the Feulgen procedure[6]. The photometric absorption by single nuclei at 546μ was measured using a Deeley type integrating microdensitometer[7,8] and this gave a measure of their DNA content in arbitrary units. A search was specially made in each print for abnormal nuclei. The larger piece of pituitary was fixed either in 10 per cent formolsublimate or, more satisfactorily, in a fixative containing chrome-alum[9]. Sections (3μ) were cut coronally at intervals through each pituitary, and were stained with the periodic acid–Schiff (PAS)-trichrome method and by a modification of an aldehyde thionin–PAS–trichrome method[10].

In each case the effects of naturally occurring oestrogens were evident after 3 months of treatment and further treatment usually resulted only in an accentuation of these effects. After ovariectomy the gonadotrophs became degranulated, enlarged and vacuolated, having the typical appearance of "castration cells"[11,12]. Treatment with any of the four oestrogens almost suppressed this change at 3 and 6 months and in the 14 month group no "castration cells" were seen. In the case of oestrone treatment for 3, 6 and 14 months the PAS-positive granules of most of the gonadotrophs consisted of a few coarse clumps capping the nucleus. With 16-epioestriol and equilenin this appearance of the PAS-positive granules was manifest at 14 months, and with oestriol, although the "castration cell" vacuoles were absent the gonadotrophs were very abundant and appeared normal with well granulated cytoplasm at 3, 6 and 14 months.

Oestrone induced so massive an increase in the number of acidophils that the glands assumed an abnormal and tumorous macroscopic appearance after 14 months of treatment. The weight of the pituitaries was greatly increased in rats treated with oestrone (Table 1). In areas of acidophil proliferation the cells had enlarged nuclei with an "empty" appearance, the chromatin forming a rim against the nuclear membrane; there was a large central nucleolus. During the normal oestrous cycle there is an increase in the number of mitotic figures in the acidophils at oestrus when increased levels of oestrogen are produced[13]. We found that only pituitaries treated with oestrone had abundant mitotic figures in the acidophils. Table 2 shows the distribution of nuclei from 14-month treated rats according to their content of DNA measured in arbitrary units with the microspectrophotometer. Only oestrone treatment had the effect of greatly increasing the proportion of nuclei with amounts of DNA greater than that of diploid nuclei ($2N$); some nuclei had amounts greater than that at the tetraploid mode ($4N$). In equilenin and 16-epioestriol treated rats, in intact controls, and in ovariectomized controls given oil, there were a few nuclei with DNA contents above the diploid amount. No nuclei with more DNA than the diploid amount could be

* Each value is the mean for three animals.

found with oestriol treatment. Treatment with each of the oestrogens resulted in the maintenance of the weight of the uteri, which was greatly reduced by ovariectomy and by ovariectomy with corn oil (Table 3).

Under the conditions of our experiment only oestrone treatment induced (1) a great increase in the numbers of acidophils, (2) the presence of numerous mitotic figures in the acidophils, (3) the presence of abundant nuclei with contents of DNA greater than the normal presumed diploid amount ($2N$) and even exceeding the tetraploid ($4N$) amount, and (4) a great increase in the weight of the pituitary gland. The presence of many mitotic figures and many nuclei with a DNA content between the $2N$ and $4N$ amounts in the oestrone treated rats indicates that the latter are probably interphase nuclei which are synthesizing DNA in preparation for cell division. The occurrence of relatively numerous nuclei with contents of DNA well above the $4N$ value suggests that the increase in the number of acidophils is not due to a continuous, but otherwise normal, stimulation by oestrogen as suggested by Clifton and Meyer[5], but that the cells are abnormally stimulated by oestrone treatment, and that some of them have assumed characteristics usually possessed only by malignant cells.

All four of the naturally occurring oestrogens showed oestrogenic activity by preventing the development of "castration cells" in the pituitary gland after ovariectomy; oestrone was the most effective and oestriol the least. Fieser and Fieser[14], however, report that the oestrogenic potency of oestrogens administered subcutaneously as determined by "bioassay in rats" is such that oestrone is greater than oestriol and oestriol is greater than equilenin; by oral administration oestriol is more active than oestrone. Furthermore, Loraine *et al.*[15] found that 16-epioestriol is less active than oestriol when assessed by the Allen and Doisy[16] vaginal smear test. In our experiment all the oestrogens maintained the weight of the uteri which fell drastically after ovariectomy (Table 3). Lauson *et al.*, however, found that in assays based on increase in uterine weight in intact immature rats oestriol is more potent than oestrone[17].

We thank the British Empire Cancer Campaign for Research for financial support and Dr. G. F. Marrian for the supply of oestrogens.

Effect of Thorazine (Chlorpromazine) on Collagen Metabolism

IN the course of an investigation of the effect of partial body X-irradiation on collagen metabolism we used thorazine (chlorpromazine) as an aid in immobilizing rats[1]. We found quite unexpectedly that the incorporation of carbon-14-labelled amino-acids into collagen was markedly suppressed during the first month, and considerably enhanced 2–4 months after the injection of the drugs. The effect of thorazine on collagen metabolism was observed in all tissues, but was most pronounced in bone collagen. Because of the involvement of bone collagen, we feel that our findings should be brought to the attention of clinicians who may be treating fracture cases with, among other drugs, thorazine, a drug which may impair the healing process.

Granulomata were induced in rats by implanting polyethylene sponges in the flanks of 50 day old Sprague–Dawley rats, by a method similar to that described by Boucek and Noble[2]. The sponges were collected after 7 days, sliced, and incubated with constant shaking in 5 ml. of Puck's medium *N*-16 containing 0·39 μc./ml. of 2-carbon-14-glycine and 5 per cent newborn calf serum in an atmosphere of 95 per cent oxygen and 5 per cent carbon dioxide. After the incubation was over, total collagen was extracted from the sponges using boiling water and the collagen thus extracted was purified by precipitation with trichloroacetic acid and acetone[3]. The purified material was dissolved in 2·0 ml. of water and a 0·1 ml. portion plated on planchets for counting in a windowless gas-flow counting system. Another portion was used for the spectrophotometric determination of the collagen content at 280 mμ using a solution of commercial gelatin as a standard. In order to correct for differences in the cellularity of different granulomata, the specific activity of collagen (c.p.m./mg) was normalized on the basis of the DNA content of the sponge, determined by the method of Webb and Levy[4].

Two types of experiments were carried out with the *in vitro* system described: (1) incubation of granulomata removed from granuloma-bearing rats injected intramuscularly 1, 24, 48 and 72 h earlier with 3·75 mg thorazine per 100 g body-weight (Table 1) and (2) incubation of granulomata from uninjected rats after addition of various amounts of thorazine to the incubation mixture (Table 2).

The data shown in Table 1 indicate that there is a significant increase in carbon-14 incorporation 72 h after the injection of thorazine. In addition, there appeared to be a slight depression of isotope incorporation 24 and 48 h after the drug was injected, which manifested itself after 3 h of incubation, although this is not highly significant. The increase in isotope incorporation on the third day after injection resembles changes seen in the intact animal long after thorazine injection. At present we cannot

Table 1. EFFECT OF INJECTION OF THORAZINE ON THE *in vitro* SYNTHESIS OF COLLAGEN

Time after injection of thorazine (h)	Incubation time (h) 1	2	3
1	183	495	788
	195	680	
24	228	246	378
	286	485	
48	254	157	545
	311	328	585
72	455	990	1,590
	545		1,687
Uninjected control	296 (270–324)	452 (282–642)	880 (650–1,135)

The figures in columns 2–4 represent carbon-14 activities expressed as c.p.m./mg of collagen per μg of DNA per g dry weight. With the exception of the control values, each activity value represents the result obtained with two granulomata from one animal, the granulomata having been incubated separately, but then combined for the isolation of collagen. In the case of the uninjected control rats the single, centred figures in columns 2–4 represent average carbon-14 activities of collagen obtained from experiments with four rats, each bearing two granulomata. As in the case of the thorazine-injected rats, the granulomata were incubated separately and then combined for isolation of collagen. The figures in parentheses represent the ranges of values obtained.

Table 2. EFFECT OF THE ADDITION OF THORAZINE TO THE INCUBATION MIXTURE

Thorazine added (μg)	Carbon-14 activity
None	1,252 ± 500*
125	2,372 ± 800
250	1,590 ± 600
500	1,443 ± 200
1,250	835 ± 150
2,500	425 ± 170

Carbon-14 activity expressed as c.p.m./mg collagen/μg DNA/mg dry weight.
* Standard deviation (based on three separate experiments).

explain this change in collagen metabolism due to the injection of thorazine.

The results shown in Table 2 demonstrate that thorazine, when supplied in sufficiently high doses (2,500 μg), has a pronounced inhibitory effect on the incorporation of carbon-14-glycine into collagen. There is no clear evidence at any time of an *in vitro* stimulation of the incorporation of labelled glycine into collagen by thorazine, as seen in the *in vivo* experiments. It is not possible to compare the drug concentrations prevailing in these *in vitro* experiments with the level of thorazine present in the granulomata after injection of thorazine, since we did not investigate the distribution of the drug in the injected rats. If one assumes a random distribution of the drug in the rat, there would be approximately 2 μg in the granuloma, a level considerably below that achieved at the lowest concentration of thorazine in the *in vitro* experiments. Since the stimulation of the incorporation of carbon-14-glycine into collagen after injection of the drug was not observed until the third day after the injection, it is conceivable that the effect of thorazine on collagen metabolism is secondary to some other effect of the drug, perhaps on the endocrines, such as on pituitary[5] or adrenal glands[6].

PHARMACOLOGY

Effects of Actinomycin *D* and Puromycin on Chromosomes of Cultured Human Leucocytes

ACTINOMYCIN *D* is a potent antibiotic with cytotoxic properties in tissue cultures[1-3] which has been used in the treatment of human neoplasms[4-9]. The action of actinomycin may depend on its capacity to bind with DNA, thus inhibiting RNA synthesis[10]. It has also been suggested that it is the synthesis of the DNA-primed RNA which is inhibited[11]. Puromycin, also an antibiotic, is believed to inhibit protein synthesis in a wide variety of organisms and tissues by causing premature release of incomplete polypeptide chains from the ribosomal system[12-20].

The purpose of the experiment described here was to investigate the comparative effects of actinomycin *D* and puromycin on mitotic activity and chromosome morphology in cultured human leucocytes. Venous blood was drawn from healthy adult donors, and a modified version of the Moorhead technique for leucocyte culture was used. The blood samples were divided into 5 ml. amounts, to which 0·05 ml. of phytohaemagglutinin (Difco, form *M*) was added to facilitate the agglutination of red cells. The plasma obtained from 5 ml. of blood was pipetted into 5 ml. of synthetic tissue culture medium (*TC* 199, Difco) containing 0·05 ml. of phytohaemagglutinin. Graded concentrations of actinomycin *D* and puromycin dihydrochloride were added to separate cultures. Each antibiotic was dissolved in *TC* 199 in the following gradation of concentrations: 0·01, 0·05, 0·1, 1·0, 2·0, 2·5 and 3·0 μg/ml. The actinomycin *D* was obtained sterile. The puromycin had to be passed through a Swinny filter because the commercial preparation was not sterile. Two drops of colchicine ($1{\cdot}0 \times 10^{-6}$ M) were added to each culture 4 h before collection. The cells were fixed in glacial acetic acid : methanol (1 : 3). Slides were flamed over an alcohol lamp and stained with Giemsa. Metaphases were examined for abnormalities in cultures ranging from low to high antibiotic concentrations. The mitotic index was determined by counting the number of metaphases per 1,000 cells.

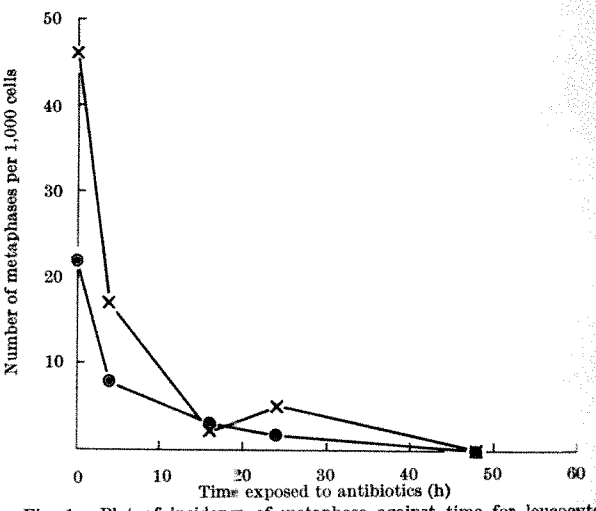

Fig. 1. Plot of incidence of metaphase against time for leucocytes exposed to 0·02 μg/ml. actinomycin *D* (○), and 3·0 μg/ml. puromycin (×)

There was complete inhibition of mitotic activity in cultures containing more than 0·02 μg/ml. of actinomycin *D*. The first noticeable effect after administering increasing amounts of the antibiotic to the cultures was a decrease in the mitotic index. It was not possible to analyse twenty-five metaphases in those cultures with more than 0·015 μg per ml. because very few metaphases were found in the higher concentrations.

No metaphases were found in cultures containing more than 3·0 μg/ml. of puromycin. Twenty-five metaphases were examined in the cultures containing 0·01, 0·05, 0·1, 1·0 and 2·0 μg/ml. of puromycin. Less than twenty-five metaphases were found in the cultures of 2·5 and 3·0 μg per ml., and so fewer than twenty-five were analysed.

Fewer cells were found in the cultures containing the higher concentrations of puromycin and actinomycin *D*. These cells tended to be in clusters, and some of them had a granular appearance. This may have been due to a toxic action on the leucocytes by both antibiotics. No morphological alterations of the chromosomes were observed, such as breaks, or the translocation-like cross-configurations produced in leucocyte cultures with mitomycin *C* (ref. 21).

To study the effects of 0·02 μg/ml. actinomycin *D* on leucocytes for varying periods of exposure up to 72 h, the appropriate amount of antibiotic was added 72, 48, 24, 16 and 4 h before collecting the cells. The same procedure was followed using 3·0 μg/ml. of puromycin. The results are shown in Fig. 1. Inhibition of all mitotic activity was most evident after the antibiotics had been in the culture for more than 24 h. No metaphases were found in the cultures exposed to the antibiotics for 48 or more hours.

The actinomycin *D* used in this experiment was obtained from Merck, Sharp and Dohme, Rahway, New Jersey; the puromycin from Nutritional Biochemical Corp., Cleveland, Ohio.

4-Cyano-2-iodo-6-nitrophenol: a New Fasciolicide

ALTHOUGH some drugs are effective against the adult liver fluke *Fasciola hepatica* in sheep and cattle, none is yet available that provides adequate control of the immature fluke at a tolerated dose rate.

For several years we have sought novel fasciolicides[1]. An interesting level of activity against the mature fluke found for the known anthelmintic 2,6-di-iodo-4-nitrophenol (disophenol) (I)[2] led us to synthesize and test a wide range of substituted phenols and their derivatives:

(I)

(II)

One of these, 4-cyano-2-iodo-6-nitrophenol (first synthesized by Mr. D. R. Broad) ('M & B 10,755') (II), showed high activity against both the adult and immature flukes and was selected for fuller evaluation[3].

'M & B 10,755' is a yellow, almost odourless, crystalline solid, m.p. 137°–138° C. It is sparingly soluble in water, but moderately soluble in most common organic solvents. The phenol is a fairly strong acid (pK_a 2·85 in water) and forms stable salts with inorganic and organic bases. The *N*-methylglucamine salt ('M & B 10,755*A*') is a yellow solid, which is freely soluble in water (65–70 per cent w/v at room temperature) giving a substantially neutral yellow solution.

The acute toxicity of 'M & B 10,755' in experimentally infected (*Fasciola hepatica*) rabbits, sheep and calves (Table 1) was established by oral dosing with a suspension of 'M & B 10,755' in tap water, and subcutaneous or intramuscular injection of a 57 per cent w/v aqueous solution of the *N*-methylglucamine salt, 'M & B 10,755*A*', containing 34 per cent w/v 'M & B 10,755'. Deaths resulting from toxicity occurred within 24 h of dosing. In the surviving sheep treated with 40 mg/kg, panting, respiration and increased body temperature were recorded. A transient local reaction followed treatment by injection and in some of the sheep and calves treated at doses above 20 mg/kg a sterile local reaction was found at the injection site. The results in breeding sheep treated every 28 days with 20 or 10 mg/kg by subcutaneous injection, starting before tupping, showed no adverse effect on oestrus or reproduction.

Table 1. ACUTE ORAL AND PARENTERAL MAXIMUM TOLERATED DOSE OF 'M & B 10,755' IN RABBITS, SHEEP AND CALVES AND THE MINIMUM EFFECTIVE DOSE AGAINST MATURE *Fasciola hepatica*

Experimental host	Maximum tolerated dose (mg/kg)		Minimum effective dose against the mature *F. hepatica* (mg/kg)	
	Oral	Subcutaneous/ intramuscular	Oral	Subcutaneous/ intramuscular
Rabbit	100	70	10	10
Sheep	75	40	50	8
Calf	75	40	50	8

In activity tests against mature *Fasciola hepatica* in rabbits, sheep and calves the compound was administered by oral dosing or parenterally, and the results (Table 1) show that in sheep and calves the compound is more potent by the latter route.

Dosing by the subcutaneous route was selected for testing against parasites of different ages. Sheep and calves experimentally infected with a single dose of 300 metacercariae produced from a laboratory-maintained strain of *Limnaea truncatula* were treated after 4, 6, 8 or 10 weeks. The effect of treatment was assessed by counting the number of mature and immature flukes found in the liver, bile ducts and gall bladder at post-mortem examination carried out 12 to 14 weeks post-infection. The results are summarized in Table 2. These show that treatment with 'M & B 10,755' at 20 or 34 mg/kg bodyweight as early as 4 weeks after infection produced a reduction in the number of flukes, and after 6 weeks 20 mg/kg eliminated the infection in the sheep. Against

Table 2. RESULTS OF THE TREATMENT WITH 'M & B 10,755' OF 4-, 6-, 8- AND 10-WEEK OLD *Fasciola hepatica* INFECTIONS IN EXPERIMENTALLY INFECTED SHEEP AND CALVES

Interval (weeks) between infestation and treatment	Dose (mg/kg) of 'M & B 10,755'*	Sheep			Calves		
		No. treated	Mean No. of parasites recovered	Percentage of Reduction	No. treated	Mean No. of parasites	Percentage of reduction

Untreated		15	101·5	—	7	91·1	—

* Administered by subcutaneous injection using a 57 per cent w/v solution of 'M & B 10,755*A*' (34 per cent w/v 'M & B 10,755').

the 10 week old infection the effective dose in both species of animal was between 5 and 10 mg/kg body weight. These data suggest that routine treatment with 'M & B 10,755' may prevent the acute disease as well as effectively control the chronic disease, produced by the mature (older than 8 weeks) fluke.

Field experiments, further to investigate the potential of the compound in the control of fascioliasis in ruminants, are in progress.

Citrinin—a Fungistatic Antibiotic and Narrowing Factor

DURING growth, fungi produce substances which have morphogenetic effects when applied to apices of actively growing hyphae. Factors which induce vacuolation, branching and other effects have been described[1]. The application of drops of culture filtrates to the margins of fungal colonies growing on agar is a suitable method for the demonstration of these morphogenetic factors, owing to the fact that developmental and ageing effects are most readily detected in this juvenile region. During a survey of culture filtrates from a large number of fungi which were being tested in this manner, one of the culture filtrates produced in the tips of the test fungus an abrupt and immediate change such that the subsequent growth of the axis was of considerably smaller diameter. The effect persisted after the treatment for more than 1 h and was followed by a gradual recovery until after 1·5–2 h the apex was again producing a hyphal tube of about the original diameter. No cytoplasmic change was evident in the treated tips. Branching was occasionally induced near the point of abrupt narrowing but was not invariably associated with the effect. The phenomenon of narrowing is of particular interest in relation to morphogenesis of the fungal colony as characteristically those hyphae produced behind the margin in the still developing but older regions of the colony are narrower than those at the extending margins. An understanding of the mechanism of hyphal narrowing could enlarge our knowledge of the process of ageing in fungi, and could also provide information helpful in elucidating the normal processes of hyphal extension growth.

The culture filtrate effective in producing narrowing in this survey was found to have become unintentionally contaminated with a species of *Penicillium*. Filtrates from pure cultures of this fungus produced the same effect, whereas those of the intended inoculum did not. After further investigation of the narrowing factor, the contaminant was identified on morphological criteria as *P. citrinum* Thom. This identification was later supported by an antibacterial spectrum test[2]. Before the morphological identification of the producer fungus the narrowing factor was isolated as a yellow crystalline compound. This later proved to be citrinin. *P. citrinum*, *IMI* 24307, was obtained from the Commonwealth Mycological Institute Culture Collection, Kew, Surrey, and when grown under conditions similar to those used for the Belfast strain it gave a similar narrowing effect and similar yields of citrinin.

In most of our studies the fungus was cultured in a liquid medium containing 7·0 g glucose; 0·5 g $MgSO_4.7H_2O$; 0·2 g potassium dihydrogen phosphate; 0·1 g ammonium nitrate; distilled water to 1 l. Then 100 ml. quantities in 500 ml. flasks were inoculated and incubated under static conditions. As measured by our biological assay of narrowing, best yields of the factor were obtained at 30° C after seven or more days. The yields of citrinin under these conditions were much lower than those reported by Hetherington and Raistrick[3] under their conditions. These workers were able to precipitate citrinin directly from their culture filtrates by adding concentrated hydrochloric acid, and they obtained yields of 1·5–2·0 g/l. Acidification of our culture filtrates gave no detectable precipitation. We first obtained citrinin by acidification of the culture filtrate and extraction with diethyl ether. The ethereal layer was separated, concentrated and extracted with a saturated solution of sodium bicarbonate. The sodium bicarbonate phase was acidified and extracted with ether. The ethereal phase contained the narrowing factor, and after removal of the ether by evaporation the solid residues were dissolved in hot ethanol and the long yellow needles allowed to crystallize out at low temperature. These crystals in aqueous solution were active in causing narrowing at a concentration of 1–2 p.p.m. At high concentrations the hyphae were killed. After characterization of the narrowing factor a simpler isolation method was adopted whereby the reduced volume of the initial acidic ether extract was shaken with a small volume of a saturated solution of sodium bicarbonate. On acidification of the aqueous phase, the solution became so saturated with citrinin as to result in a heavy precipitation of microcrystals. These were filtered, washed, dried and recrystallized from ethanol. The crystals obtained in this way from the Belfast strain of *P. citrinum* melted at 166°–168° C with obvious decomposition. Analysis of the carbon and hydrogen content closely agreed with that reported for citrinin[5]. Further proof of identification was afforded by infra-red and nuclear magnetic resonance spectra. The infra-red spectrum agreed with that published for citrinin by Kováč *et al.*[4].

The standard test fungus used in our survey and in subsequent investigations of citrinin as a narrowing factor was *Aspergillus niger* v. Tiegh. grown as previously described[5]. Other fungi tested in the same way and found to respond to citrinin solution by narrowing were *Pythium mamillatum*, *P. proliferum*, *P. ultimum*, *Phytophthora parasitica*, *Absidia glauca*, *Mortierella* sp., *Mucor hiemalis*, *M. plumbeus*, *Rhizopus stolonifer*, *Neocosmospora vasinfecta*, *Neurospora crassa*, *Serdaria fimicola*, *Trichoderma viride* and *Armillaria mellea* as well as the producer strain of *Penicillium citrinum*. Thus representatives of each major group of the fungi show the response, as does the organism which produced the factor. The production of citrinin is not confined to *P. citrinum*. Other producer species are *P. velutinum*[6], *P. steckii*[7], *P. notatum*[8], *P. lividum*, *P. phaeojanthinellum*, *P. chrzaszczi*, *P. implicatum*, *P. citreosulphureum*, *Aspergillus terreus*[9] and *A. candidus*[10]. It is not possible at this stage to know what significance citrinin might have as a general fungal morphogen as there is no record of any search for citrinin in genera outside the Aspergillales.

In addition to the investigation of the action of citrinin on hyphal tips we are undertaking a study of its effects on the germination of fungal spores. Citrinin has been tested in 1·5–50 p.p.m. solutions on sporangiospores of *Rhizopus stolonifer*. In a concentration of 1·5 p.p.m. the spores germinated much more slowly than in controls and the germ tubes were more branched. However, the hyphae were of regular diameter. At concentrations of 6·25 and 12·5 p.p.m. there was some distortion of growth with a very irregular hyphal diameter and a sinuous out-

line. There was a tendency for the average germ tube length to decrease with an increasing concentration of citrinin. At 25 p.p.m. the spores swelled considerably and produced papillae but no germ tubes. There was no indication of germination at 50 p.p.m. After a further incubation period of 12 days the spore suspensions were re-examined, and in solutions of 12·5–50 p.p.m. no further development had occurred since the 24 h period. At the end of 13 days the spores and germlings were found to be still viable and capable of normal growth on transfer to a suitable medium.

Citrinin, which was isolated in 1931 (ref. 3) and first described as an antibacterial antibiotic in 1941 (ref. 11), has been thoroughly investigated for activity against bacteria, and has also been tested against bacteriophage[12], sarcoma tissue[13], amoebae[14], paramoecia[15], animal cells[16], and higher plant cells[17]. Considering that it is a fungal product it is surprising that it has not been more thoroughly investigated in relation to its effects in fungi. The only two records which we have been able to find relate to the fact that it was found to inhibit the formation of adaptive enzymes in the metabolism of phenolic compounds by spores of soil fungi[18], and that some plant pathogenic fungi show growth inhibition when inoculated to nutrient agar containing 500–1,000 p.p.m. citrinin[19]. Other fungi were little affected, and at concentrations lower than 500 p.p.m. citrinin had no significant effect on any of the fungi. These media containing citrinin, however, appear to have been heat sterilized and it is known that citrinin is thermolabile. Our own results indicate that for at least one fungus the minimum fungistatic concentration is of the same order as the published minimum inhibitory concentration for *Staphylococcus aureus* (30–40 p.p.m.).

Because of its toxicity to animal tissues, citrinin appears to be unsuitable for chemotherapy as applied orally or by injection. However, citrinin has been reported to be effective as an ointment or powder for surface application in skin affections[20,21], and it may have no adverse effect when applied to the cornea or mucous membranes[22]. Because many fungal infections of animals are superficial, citrinin may have possible applications in the control of such diseases.

We thank the Medical Research Council for supporting this work.

HISTOCHEMISTRY

Enzyme Histochemistry of Developing Human Muscle

This communication reports an attempt to establish the sequence of events in the process of differentiation of developing human muscle into the two types of fibre.

By histochemical methods it is possible to recognize two basic types of muscle fibre in human muscle[1–3]. It was suggested that these fibres be called type I (rich in reduced nicotinamide–adenine dinucleotide (NADH)–diaphorase and poor in phosphorylase) and type II (rich in phosphorylase and poor in NADH–diaphorase), respectively. Subsequent authors have shown that type II fibres are also rich in mitochondrial α-glycerophosphate dehydrogenase[4] and in myosin ATPase[5].

In an earlier report on developing muscle[6] it was noted that, in the muscle of the newly born infant, as in certain newborn animals, the fibres are already fully differentiated, as in the adult, into the two basic fibre types, which are present in about equal numbers.

Twenty-one muscle specimens from twelve newly born full-term human infants and forty muscles from twenty-one newly born premature human infants (with birth weight less than 2,500 g) were obtained at autopsy. All had died within 48 h of birth.

Various muscles were dissected from seventeen human foetuses, ranging in gestation from 12 to 26 weeks. These were obtained mainly from therapeutic abortions, but a small number resulted from spontaneous abortions.

In addition to routine histological stains (haematoxylin and eosin, Van Gieson, and periodic acid–Schiff), the NADH–diaphorase[7], phosphorylase[8] and myosin adenosine triphosphatase[9] reactions were carried out. In the newborn full-term infants all muscles showed a differentiation into two types, as in the mature adult muscle (Fig. 1). The newborn premature infants also showed a subdivision of the muscles into two fibre types, and, with the exception of one infant of 26 weeks gestation (weighing 840 g), the distribution of the two types of fibre was approximately equal. The one exceptional infant had a disproportionately large number of type II fibres (poor in NADH–diaphorase) and a very small proportion of type I fibres.

Of the seventeen foetuses, five showed a very similar pattern. These were the five largest in the series and ranged in gestation from approximately 20 weeks to 26 weeks. In all their skeletal muscles there was a differentiation into two fibre types, but there was a disproportion between the two types. The vast majority belonged to type II and only a small proportion were of type I (Fig. 2).

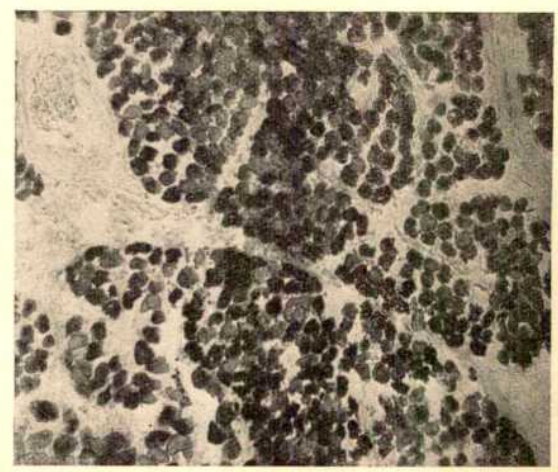

Fig. 1. Section of quadriceps of full-term new-born infant. (Phosphorylase reaction. × 100)

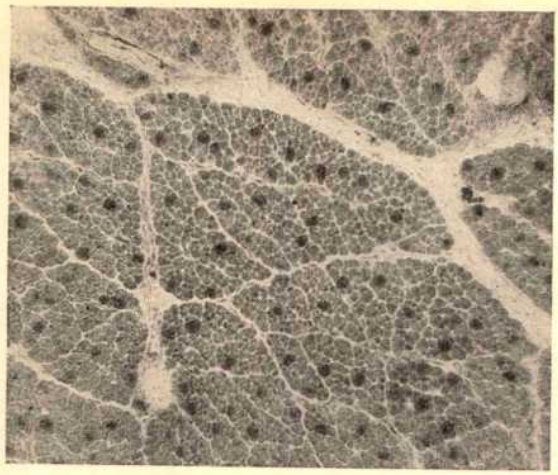

Fig. 2. Section of triceps of human foetus after 23 weeks' gestation. (NADH-diaphorase reaction. × 100)

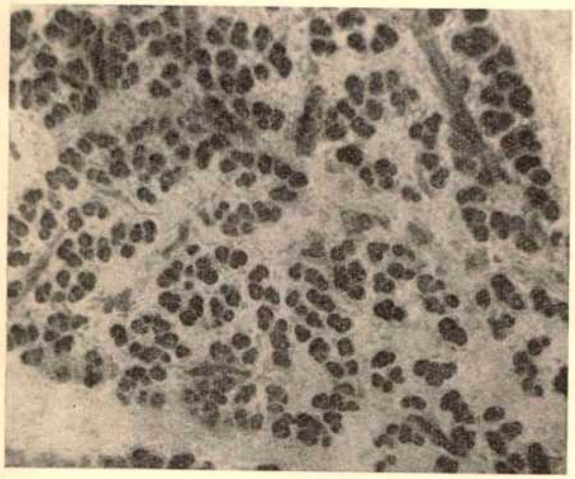

Fig. 3. Section of glutei of human foetus after 13 weeks' gestation. (ATPase reaction. × 100)

The proportion of type I fibres ranged from about 3–10 per cent of the total. These type I fibres were in the upper range of fibre diameter.

The remaining twelve foetuses, ranging in gestation from 12 to 18 weeks, did not show this pattern of differentiation. In some of the muscles all the fibres reacted uniformly for a particular enzyme system. In others there was some variation in enzyme activity of the fibres. However, this variation did not follow any consistent pattern and frequently clusters of either strongly or weakly reacting fibres occurred together (Fig. 3). Despite the variation in enzyme activity, these fibres could not be correlated enzymatically with the type I and type II fibres of mature muscles, as some fibres rich in ATPase were also rich in NADH–diaphorase and phosphorylase, and conversely.

Human foetal muscle can thus be divided into three phases of development by histochemical enzyme stains. In phase 1, approximately 12–18 weeks' gestation, there may be some variation in enzyme content of different fibres but this is not consistent and there is no clear cut sub-division into type I and type II fibres. In phase 2, approximately 20–26 week's gestation, there is a clear cut sub-division into type I and type II fibres, but type I form only a small proportion of the total and are larger in diameter. In this phase the type I fibres correspond in appearance and distribution to the so-called *b* fibres described by Wohlfart[10] in the developing muscle. In phase 3, from about 30 weeks' gestation onwards, there is a sub-division into type I and type II fibres, giving a checkerboard pattern, as in mature adult muscle, and with an approximate equal distribution of the two types.

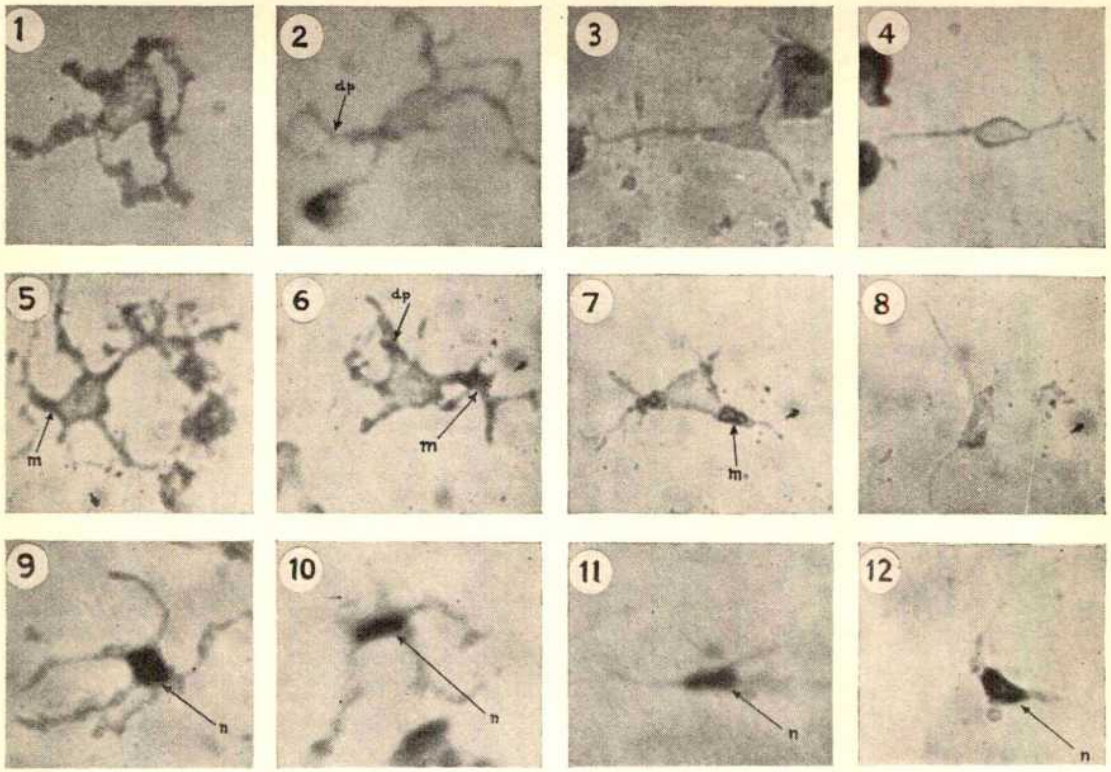
Staining and Typing of Langerhans' Cells in the Skin of the Black Guinea-pig



RECENTLY I described[1] some cytomorphic forms of the epidermal Langerhans' cells[2–4] in the black guinea-pig. This communication reports a method of classifying these cells.

A saline suspension of the digest of the pure epidermis from the ear of the guinea-pig, prepared according to the method devised by Shukla, Karkun and Mukerji[5], is mounted on albuminized slides and treated with (*a*) a solution of 3,4-dihydroxyphenylalanine (DOPA) according to Laidlaw and Blackberg[6], (*b*) Masson-Fontana stain for melanin according to Pearse[7] and (*c*) Harris's haematoxylin and eosin and Mayer's haem-alum stain for nucleus as described by McManus and Mowry[8]. The Langerhans' cells, one of the constituents of the epidermal digest, become stained by this process and can be observed under a bright field microscope. The cells possessing five, four, three and two dendritic processes are identified and classified as Type I, II, III and IV, respectively. A summary of the characteristic features of each type of Langerhans' cells is given in Table 1.

The Langerhans' cells of Types I–IV show a gradual reduction in the size, number of dendritic processes and the cytoplasmic contents (Figs. 1–12). These cells demonstrate a degenerative change in the internal structure.

Table 1. CHARACTERISTIC FEATURES OF TYPES I–IV LANGERHANS' CELLS

Characters examined	Langerhans' cell types I	II	III	IV
Nucleus				
Shape	Egg shaped	Oval	Triangular	Fusiform
Size (length × breadth in μ)	7 × 5	7 × 4	6 × 4	6 × 3
Consistency	Vesicular	Vesicular	Shrunken	Shrunken and crenated
Stainability with haematoxylin	Basophilic	Basophilic	Deeply basophilic	Deeply basophilic
Cytoplasm				
Quantity	Ample	Reduced	Thin rim around nucleus	Scanty
Stainability with eosin	Slight	Slight	Weakly positive	Positive
	±	±	+	+ +
Location of melanin	Periphery of the body and dendritic processes	Dendritic processes	Absent	Absent
DOPA reaction	Positive at periphery of the body and dendritic processes	Positive at dendritic processes	Negative	Negative

Figs. 1–4. Types I–IV Langerhans' cells after DOPA reaction. It is weakly positive in Type I, weaker in Type II and negative in Types III and IV

Figs. 5–8. Types I–IV Langerhans' cells after Masson-Fontana stain, which demonstrates melanin (*m*) in the dendritic processes (*dp*) and periphery of the cell in Type I, in the dendritic processes in Type II, at the roots of dendritic processes in Type III. Type IV cell does not show melanin granules

Figs. 9–12. Types I–IV Langerhans' cells after Mayer's haem-alum stain. The large vesicular nucleus (*n*) in Type I is gradually reduced in size in Types II, III and IV

The well defined oval, vesicular, basophilic nucleus in Type I gradually give way to the triangular form in Type III (Fig. 11) which in turn is transformed to the fusiform and deep and diffusely staining nucleus in Type IV (Fig. 12). The sparse peripheral melanin in Type I (Fig. 5) is gradually reduced in quantity in Type II (Fig. 6) and Type III (Fig. 7) and becomes obliterated in Type IV (Fig. 8). Again, cells of Types I–IV show a progressively weak DOPA reaction which indicates that there is a gradual regression in their capability to synthesize melanin (Figs. 1–4).

The changes observed in the Langerhans' cells of Types I–IV are reminiscent of the ischaemic degeneration of the pyramidal cells of the cortex[9], when the cells gradually disintegrate and disappear. Billingham and Medawar[4] postulated a similar type of degenerative extinction for the Langerhans' cells. The observations made here support his view.

I thank R. K. Saraut for his technical assistance in this work.

PHYSIOLOGY

Evidence for the Discharge of Cholinesterase into Canine Eccrine Sweat

AN outstanding feature of the eccrine sweat glands in the paw of the dog is that pseudo-cholinesterase is abundant in their secretory cells[1–3]. During an earlier investigation[3] it was noticed that the inside of the lumen of the sweat ducts in the toe-pads of the dog often gave histochemical reaction for pseudo-cholinesterase. This finding led us to assume that the cholinesterase in the gland cells might be discharged into sweat. The work reported here provides evidence in favour of this assumption.

Thirty-one experiments were performed on seven puppies aged 2–10 months and on one adult dog aged about 2 years, all of which retained good ability to sweat on the foot pads spontaneously as well as in response to local application of sudorific agents such as acetylcholine or acetyl-β-methylcholine (mecholyl).

The sweat droplets, which were produced on the toe-pads or the central pads either spontaneously or by local injection of mecholyl at concentrations of 10^{-4}–10^{-5} g/ml., were collected with a fine glass capillary tube under a stereomicroscope. Each sample of sweat (about 0·1–0·2 mg) was added to 2 ml. of an incubation solution of the type used in Gomori's modification[4] of Koelle's histochemical method for cholinesterase[5–7]. Acetylthiocholine and butyrylthiocholine were used as substrate for the enzyme. Within half an hour of incubation at 37° C with either substrate, the solution exhibited a slight but definite white cloudiness, which became increasingly intense as the incubation was prolonged. This turbidity was found to result from the formation of fine rod-like or needle-shaped crystals in the incubation solution. If before

incubation eserine salicylate was added to the solution at a final concentration of 10^{-5} M, no such sedimentation was observed, which indicates that this reaction probably results from cholinesterase activity in the sweat and that the precipitated crystals are copper-thiocholine.

In another series of experiments, the sweat which was secreted spontaneously or by stimulation with mecholyl was blotted on to a piece of absorbent paper. After it had been dried for a few hours in the refrigerator, the paper was treated according to the histochemical technique used to demonstrate the presence of cholinesterase in tissue sections[4]. Following incubation for about 4–5 h at 37° C with either acetylthiocholine or butyrylthiocholine, the paper was dipped into a solution of 0·2 M ammonium sulphide. A marked dark brown colour (indicating the production of copper sulphide) developed on the paper at the sites where the sweat was absorbed (Fig. 1 *A* and *B*). Incubation with butyrylthiocholine always produced stronger staining than with acetylthiocholine, and both reactions were found to be completely inhibited by 10^{-5} M eserine salicylate, and further by diisopropylfluorophosphate (DFP) at concentrations as low as 10^{-8} M.

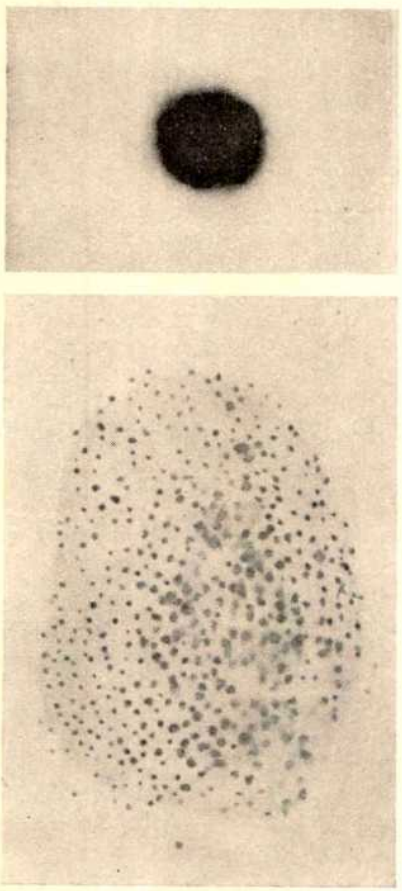

Fig. 1. Staining reaction caused by cholinesterase contained in the canine eccrine sweat. *A*, The sweat collected with a glass capillary tube was absorbed on to a piece of blotting paper and incubated with butyrylthiocholine for 4 h. The region where sweat was absorbed showed strong cholinesterase reaction. *B*, A piece of smooth-surfaced absorbent paper, which had been pressed for about 20 sec to a toe-pad showing profuse sweating, was incubated with butyrylthiocholine for 5 h. Note many stained dots revealed at the sites where the sweat droplets were absorbed

As a control experiment, normal saline was placed on the foot pad showing no sweating for a certain period of time, and tested in a similar manner to the other experiments. But neither sedimentation nor staining reaction was obtained with either substrate.

From these findings it is evident that the eccrine sweat from the paw of the dog contains cholinesterase and that it is almost exclusively of the pseudo-type, which is identical in its properties with the cholinesterase detected in the glandular tissues[3]. Furthermore, the cholinesterase activity in the sweat gland coil was histochemically found to be reduced after profuse sweating. All these findings, when taken together with the previous observation that the lumen of the sweat duct was often plugged with a substance reactive for pseudo-cholinesterase[3], suggest that the intracellular cholinesterase in the canine eccrine sweat glands is actually discharged into the glandular lumen in association with the production of sweat.

In this connexion it will be recalled that the pancreas of the dog also characteristically contains pseudo-cholinesterase in the alveolar cells and that it is discharged into the pancreatic juice[6]. The physiological significance of the presence of pseudo-cholinesterase in the dog's eccrine sweat glands as well as of its discharge into the sweat remains uncertain and requires further investigation.

I thank Prof. M. Wada for his advice in preparing this report. I also thank Hoffmann–La Roche, Inc., for generous supplies of acetylthiocholine and butyrylthiocholine, and Merck and Co., Inc., for DFP.

Enzymatic Activity of L-Glutamic Dehydrogenase in Liver Mitochondria of Adult and Foetal Rats

CONSIDERABLE differences in the radioactivity of carbon dioxide expired by liver slices of mother and foetal rats, after incubation with 1-^{14}C-L-glutamate, indicated a lower enzymatic activity of the L-glutamic-dehydrogenase (GDH) of the foetal liver compared with the adult liver[1]. The low activity of a large number of enzymes in foetal organs is known, but the oxidative enzymes generally are an exception, and usually show a higher activity in foetal than in maternal organs (for a comprehensive survey, see ref. 2). An increase in the activity of GDH was observed during foetal development in the central nervous system of pigs and monkeys[3].

We examined livers newly removed from healthy gravid rats and their foetuses, from the seventeenth to the twenty-second day of pregnancy. The tissue was broken down in a glass–'Teflon' homogenizer in ten volumes of 0·25 M sucrose, and afterwards centrifuged for 10 min at 600*g*. The mitochondrial fraction was obtained from the residue by centrifuging twice for 10 min at 10,000*g*. We added one volume per cent of 'Triton X 100' to the last fraction. Activity was determined by a modification of the method of Strecker[4] in a Zeiss spectrophotometer at 340 nm and 25° C in the following medium: 2·35 ml. 0·2 M phosphate buffer, *p*H 8·3, 0·5 ml. 10^{-3} M nicotinamide-adenine dinucleotide (NAD), 0·1 ml. 10^{-2} M potassium-L-glutamate and 0·05 ml. mitochondrial suspension. Activity was measured in ΔE_{340}/min mg protein, and the amount of protein in the mitochondrial suspension was determined after Lowry[5].

Table 1. ACTIVITY OF L-GLUTAMIC DEHYDROGENASE (ΔE_{340}/MIN MG PROTEIN) IN MITOCHONDRIA OF MATERNAL AND FOETAL RAT LIVERS

Day of pregnancy	Mothers: Activity and standard deviation	Mothers: No. of experiments	Foetuses: Activity and standard deviation	Foetuses: No. of experiments
17	355 ± 50·7	7	105 ± 37·6	5
18	431 ± 63·2	5	157 ± 36·1	4
19	366 ± 55·0	17	172 ± 55·1	9
20	430 ± 36·7	12	211 ± 87·5	9
21	392 ± 28·6	12	224 ± 49·5	8
22	394 ± 44·8	9	321 ± 76·8	9

The results are given in Table 1. On the twenty-first day the activity of GDH in the foetal livers was still considerably lower than in the maternal ones; approximately similar values were obtained only for the twenty-second day. The oxidation of L-glutamate is thus inhibited, both with GDH and by way of transamination, since a level of transaminase activity comparable to that of the adult is reached only at birth. However, this means that more glutamate is available for protein synthesis—an important reason for the relative resistance of the foetus to a maternal lack of protein, which has been shown experimentally[6]. The low activity of GDH in foetal liver mitochondria accords with the high respiratory quotient of foetal livers[7], which indicates an almost exclusive oxidation of carbon hydrates.

Adrenergic Beta-receptor Blockade and Anaerobic Metabolism

IT is known that adrenaline accelerates glycogenolysis in liver and in muscles, which leads to an elevation of the concentration of blood sugar and blood lactate[1]. During work (and especially with high work loads) there is a substantial increase in the concentration of blood lactate, which is mainly produced in the working muscles[2]. This can in part arise from increased adrenergic activity during work. The purpose of the present investigation was to test this assumption by means of an adrenergic beta-blocking agent.

In four cases, the arterial lactate concentration was studied at rest, during work and 3 min after work. They were determined again after oral administration of 15–20 mg propranolol, an adrenergic beta-receptor blocking agent. At rest, the mean lactate concentration was 0·69 mmole/l. and this remained unchanged after propranolol. During heavy work, the mean lactate concentration was 3·00 mmole/l. and 3 min afterwards was 2·71 mmole/l. Both these figures were lower after propranolol (mean = 2·16 mmole/l. and 1·77 mmole/l., respectively). The decrease was significant ($P < 0·01$) during the blockade for eleven out of the twelve samples. It seems that the effect of adrenergic activity on the metabolism, especially during and shortly after muscular work, is at least to some extent an effect of beta-receptors.

Patterns of Spontaneous Rhythmic Activity within Various Thalamic Nuclei

THE generation of spontaneous rhythmic activity has been studied by simultaneous recording with four microelectrodes (4 M sodium chloride, 1–3 M Ω), either arranged in a square with sides of 1·2–4·4 mm, or in a straight line with spacings of 1·2–3 mm.

With adult cats, which had been lightly anaesthetized with 40 mg sodium pentobarbitone/kg body-weight, spontaneous periods of rhythmic activity (spindles) were recorded from various thalamic nuclei, as described earlier[1]. The activity consisted of groups of cell discharges

Fig. 1. *A*, Generalized thalamic spindle. Rhythmic activity obtained by four microelectrodes (1–4), 1·5 mm apart, placed along a frontal line, and 7·25 mm under the dorsal surface of the thalamus. The vertical lines of the upper four traces indicate the spikes in the corresponding microelectrode records. *B*, Localized thalamic spindle. Recording as in *A*, with a period of rhythmic activity in trace 1 only, followed by local activity in trace 3 only. The start of a generalized spindle can be seen on the right-hand side. *C*, Duration of spindle activity recorded from the same four electrodes as in *A* and *B*, plotted as thick horizontal bars. Thin lines facilitate a comparison of the onset and stop of spindle activity at the different electrode locations. *D*, *E* and *F*, Three examples of generalized spindles. Time from an arbitrary 0-point along the ordinate, the time between successive bursts of spike discharges along the abscissa. Electrode location given by filled circle in insets. In *D*, the spindle frequency is similar in all locations, although the onset varies. In *E* and *F* the spindle frequency is different at various electrode locations, and sometimes alters during the spindle

followed by a positive wave, the sequence repeating itself from three to about twenty times (Fig. 1 *A* and *B*).

In most experiments, spindle activity was obtained from all electrode tracks, irrespective of their location in the thalamus. Contrary to the location of the slow 8-sec waves recorded by Morison *et al.*[2], spontaneous thalamic spindles occurred more frequently in laterally and ventrally situated nuclei than in more medial and dorsal groups.

Fully developed spindle sequences often occurred in one electrode location without any concomitant activity at the others (localized spindles, Fig. 1*B*). They could occur at all electrode sites.

However, rhythmic activity frequently occurred almost simultaneously in all four electrode locations (general thalamic spindles, Fig. 1*A* and *C*). Although an approximate simultaneity was recorded, the start of the spindles obtained by the various electrodes differed from some milliseconds to a second (Fig. 1*C*). In each spindle, the particular electrode position in which the rhythmic activity first appeared was determined. Such "leading" was observed at all thalamic locations, but the tendency to lead was greater in the lateral nuclei than in the medial ones. Furthermore, the internal spindle frequency and the rate of spindle occurrence was often higher in lateral than in medial thalamic nuclei (Fig. 1*D*, *E* and *F*), and higher in ventral than in dorsal locations. Typical spindle activity could be recorded from n. ventralis postero-lateralis and the peri-cruciate cortex after removal by suction of the medial 3 mm of the thalamus. Cell groups, separated by 1·2–2 mm, frequently discharged in a phase-locked manner, indicating driving of one cell group by the other, or of both by a common pacemaker.

The evidence reported does not support the idea of one or more medial thalamic nuclei serving as an indispensable and common pacemaker area for the rhythmic thalamic and cortical 10/sec activity. On the contrary, the possibility of rhythmic activity starting from virtually all thalamic nuclei leads to a concept of many facultative pacemaker areas within the thalamic complex. Given certain conditions, rhythmic activity may spread from one thalamic nucleus to others by projection axons, thus giving a general thalamic spindle which may influence much of the cerebral cortex. When rhythmic activity remains local, the spindle activity is found in one thalamic group and in its restricted cortical projection area only.

Synaptic Delay and Conduction Time in Brain during Exposure to Simulated High Altitudes

RELATIVELY few techniques are available for the investigation of the long-term effects of physiological variables on conduction times and synaptic delay in the brain. The lateral olfactory tract (LOT) and prepyriform cortex provide a system whereby these parameters may be measured in rats chronically implanted with electrodes[1]. Fibres of the LOT synapse with dendrites of the prepyriform pyramidal cells[2]. When the LOT is electrically stimulated by a single shock, both the presynaptic LOT potential and the postsynaptic prepyriform response may be recorded from electrodes placed in the prepyriform cortex (Fig. 1). As the LOT potential first approaches and then invades the recording area, the adjacent cortex acts first as a current source and then as a sink; hence the presynaptic potential is biphasic—first positive, then negative. The time from stimulus artefact to negative crest of the presynaptic potential is a measure of conduction time along the LOT and the time from the negative peak to beginning of the prepyriform response is a measure of synaptic delay (Fig. 1).

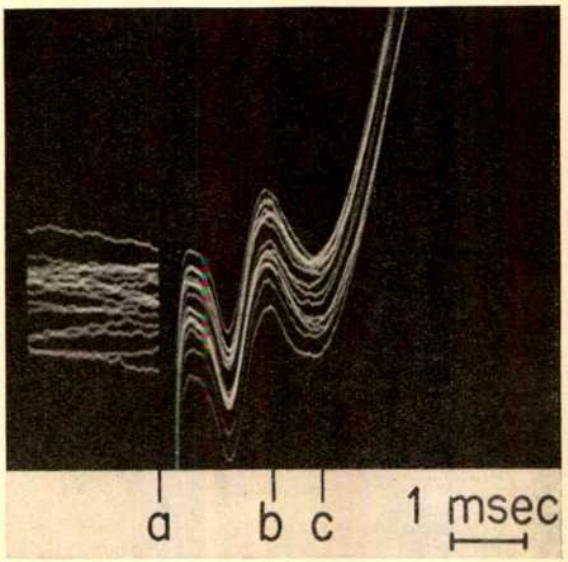

Fig. 1. Pre- and post-synaptic potentials recorded in the prepyriform cortex after electrical stimulation of the lateral olfactory tract (LOT). The initial low amplitude biphasic (positive-negative) response after the stimulus artefact is the potential of the LOT. Only the beginning of the prepyriform response is shown. The time from stimulus artefact to negative crest of the LOT potential (*a*–*b*) measures conduction time along the tract. The time from crest of the LOT potential to beginning of the prepyriform response (*b*–*c*) measures synaptic delay between fibres of the LOT and prepyriform pyramidal cells. Latency of the prepyriform response is the time from *a* to *c*

The susceptibility of synaptic transmission and conduction rate in the brain to the deleterious effects of short-term exposure to high altitudes has been demonstrated[1], but the effects of exposure for several days have not previously been investigated. Therefore, in the present experiments, the effect of exposure for 3 days to simulated altitudes of 3,800 m (12,500 ft., 475 mm of mercury pressure) and 5,490 m (18,000 ft., 380 mm of mercury pressure) on conduction time along the LOT and synaptic delay between tract and cortex were investigated in twelve rats chronically implanted with electrodes. Control pressures were 755 mm of mercury. General procedures for implantation of electrodes, electrical stimulation and recording, and simulation of high altitudes have been described previously[3]. Electrodes were bipolar (No. 26 wire, 1 mm tip separation). Rectangular pulses (0·03 msec duration, at twice the threshold intensity—usually 500 μamps) were delivered to the electrode in the LOT by means of a 'Tektronix' pulse generator and stimulus isolation unit. Responses were amplified with a 'Grass' Model *P5* alternating current pre-amplifier and were photographed with an oscilloscope camera. Experimentation was begun 1 month after implantation, when electrical activity had stabilized. Six different rats were exposed to each altitude.

Pre-exposure control means and standard errors were as follows: 0·94 ± 0·02 msec for conduction time along

the LOT; 0·60 ± 0·01 msec for synaptic delay; and 1·54 ± 0·04 msec for total latency. During exposure for 3 days to either altitude, conduction time, synaptic delay and total latency were significantly (t test, $P < 0.05$) prolonged after 2, 24, 48 and 72 h at altitude (Fig. 2). A greater percentage increase in synaptic delay than in conduction time was observed at both altitudes: synaptic delay was increased 24–32 per cent and conduction time 11–17 per cent at 5,490 m; synaptic delay was increased 15–23 per cent and conduction time 5–9 per cent at 3,800 m. The degree of change in total latency was intermediate between the changes in synaptic delay and conduction time. None of the indices measured showed any improvement with time at altitude; rather, the degree of change was slightly greater toward the end of the 3 days. After return to sea level pressures, conduction time and synaptic delay returned to normal more rapidly after the stay at the lower of the two simulated altitudes: values did not differ significantly from control levels 1 h after return from simulated 3,800 m altitude, but were still significantly prolonged 1 h after return from 5,490 m. All values were within 2 per cent of pre-exposure control levels 24 h after arrival at sea level pressure.

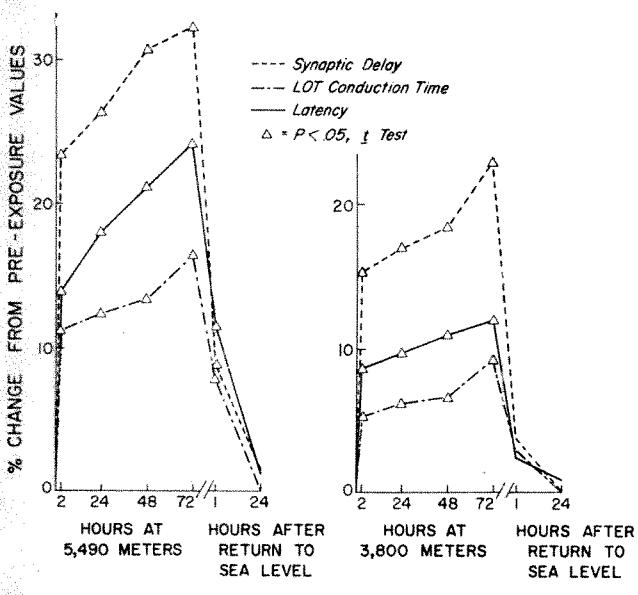

Fig. 2. Effects of exposure for 3 days to two simulated high altitudes and of return to sea level pressures on synaptic delay between fibres of the lateral olfactory tract (LOT) and prepyriform pyramidal cells, on latency of the prepyriform response, and on conduction time along the LOT. Values are expressed as percentage change from pre-exposure control values

Most of the previous investigations of hypoxia and synaptic transmission have been concerned with the effects on autonomic or spinal synapses of stagnant hypoxia due to circulatory arrest with a resultant accumulation of carbon dioxide, and have emphasized that peripheral synapses are relatively resistant to the effects of this type of hypoxia[3]. The present results show that the hypoxia of high-altitude exposure prolongs synaptic delay and conduction time in a brain system, even at the relatively moderate altitude of 3,800 m. Also, synaptic delay is altered to a greater degree than is conduction time at both altitudes, in agreement with previous observations on the effects of 2-h altitude exposure[1]. No doubt these types of changes contribute to the disturbances of central nervous function observed at altitude[3]. An important additional finding of the present experiments is that the prolongation in synaptic delay and in conduction time did not improve during the 3 day exposure to either altitude, but in fact tended to become even greater with time at altitude. However, despite the rather marked changes at altitude, the return to normal values occurred rapidly after descent to sea level pressures.

Isolation and Analysis of Adenovirus 12 Sub-units from Adenovirus Type 12-infected Cells

THE isolation of adenovirus 12 group-specific ("A") and type-specific ("C") antigens has been described by Huebner *et al.*[1] The method used for isolation of the sub-units was step by step elution from columns of diethylaminoethyl cellulose (DEAE). Because the amount of material available at a given time varied, reabsorption was less important in this procedure than with gradient elution procedures. Eluent changes were regulated by a series of tests using cell protein alone in order to eliminate the possibility of widening or tailing of bands. Virus-antigen mixtures were equilibrated with 0·01 M phosphate buffer at 6·8 *p*H before application to the column of DEAE, which was prepared in 0·01 M phosphate buffer at *p*H of 7·2. All operations were carried out in a cold room. Sodium chloride solutions were prepared in 0·01 M phosphate buffer at 6·8 *p*H so that there was a constant *p*H but an increase in salt concentration during elution. An investigation of the effectiveness of changes in salt concentration versus changes in *p*H with cell protein showed that a constant *p*H was desirable and that changes in salt fronts were predictable. It was necessary to re-cycle eluates once or twice over fresh columns in order to obtain purified material in single peaks. A critical aspect of the procedure was the resin exchange capacity of 0·56 m. equiv./g.

A model 130 'Spectrochrom' analyser (Beckman Instruments, Inc.) was used in co-operation with the Dairy Products Laboratory, Department of Agriculture. The adenovirus 12 sub-units isolated by triple cycling from DEAE columns, as already described, were each fractionated on 'Sephadex *G*-200' prepared with phosphate-buffered saline and eluted under constant *p*H of 7·6 and constant conductivity. A precision dual-beam spectrophotometer was incorporated into the 'Spectrochrom' analyser which made it possible to scan the 'Sephadex *G*-200' column effluent at any three wavelengths. One hundred drops were collected in each tube and simultaneously monitored at 220, 280 and 540 mμ. The flow rate was about 12·5 c.c./h. Seventy-five samples were collected. Each peak was analysed by complement-fixation tests of pooled, concentrated eluents; randomized samples of pooled, concentrated eluents were used throughout the separation with the 'Spectrochrom' as controls (see legends on Figs. 1 and 2). By means of this molecular sieve operation, and using known standards which included serum proteins, milk proteins and certain enzymes, it was possible to determine the molecular weight (calculated at the peak) of the materials in question[2].

Figs. 1 and 2 give some results of 'Spectrochrom' studies of adenovirus type 12 "A" and "C" antigens. Fig. 1

shows the 'Spectrochrom' analysis of separation on 'Sephadex *G*-200' of adenovirus type 12 "A" antigen (group) which had been purified by triple cycling on DEAE anionic exchange cellulose. By direct calculation, the molecular weight of adenovirus type 12 "A" antigen was found to be 190,000. Analysis by complement fixation confirmed the biological specificity of this group-specific antigen in that neither the type-specific nor the virus-induced antigens associated with cells could be demonstrated (see legend, Fig. 1).

Fig. 2 shows the separation obtained for DEAE triple-cycled purified adenovirus 12 "C" (type-specific) antigen. The calculated molecular weight of "C" antigen (peak II) was 63,000. Complement-fixation tests of the purified type-specific antigen (see legend, Fig. 2) also confirmed our previous observation[1] of the presence of antibody to adenovirus 12 type-specific ("C") antigen in broad reacting hamster tumour antisera. Complement fixation tests were negative with narrow reacting hamster tumour antisera which gave specific measurements for the presence of virus-induced antigenic material associated with cells. By means of electron microscope analysis, Valentine and Pereira[3] had been able to conclude that the molecular weight of the adenovirus type 5 "A" antigen was 210,000, while that for the "C" antigen was 70,000. Another component (Fig. 2), however, was eluted before and in connexion with "C"; the molecular weight of this component (peak I) was calculated to be 137,000. It is not known at this time what this component might be, as no complement fixation reactions were seen with broad and narrow reacting hamster tumour antisera or with group specific antisera (see legend, Fig. 2).

By the use of a 0·25 cm cuvette path length, the 540 mμ wavelength was monitored in order to rule out any interference that might arise from coloured material. It can be seen in Figs. 1 and 2 that the group specific adenovirus 12 antigen consisted of 220 mμ material with one-quarter 280 mμ material, whereas the type-specific adenovirus 12 antigen consisted mainly of 220 mμ material.

We thank the following for technical assistance: H. C. Turner for complement-fixation testing, A. Uter and A. Persi for column chromatography and J. Salasin, Dr. Byron Leach and Dr. Kenneth Fox for 'Spectrochrom' analysis.

A Method for the Rapid Assay of Newcastle Disease Virus

METHODS at present available for the detection and quantification of infectious Newcastle disease virus (NDV) particles include plaque assays[1,2], the development of haemagglutinating activity and/or death of fowl embryos[3], the appearance of cytopathic effects[4], and the enumeration of virus infected cells by fluorescent antibody staining[5]. With the exception of the last technique, all these methods require a minimum of 3 days for adequate evaluation. The adsorption of erythrocytes to infected cell monolayers as a means of detecting certain non-cytopathic myxoviruses[6] suggested to us a method for titrating NDV. This communication reports an assay for infectious

NDV based on the ability of this virus to initiate foci of haemadsorbing cells. Results from such a titration can be accurately determined 24 h after inoculation of the virus on to susceptible monolayers. The rapidity and reproducibility of this assay technique have made it exceptionally useful in our studies on the synthesis and properties of NDV.

The *HEp*-2 cells used in this study were propagated in Eagle's minimal essential medium containing 10 per cent inactivated calf serum. Two strains of NDV, California 11914 and *OS* (obtained from D. A. Wolff, Ohio State University), were used in this investigation and yielded identical results. The assay was accomplished as follows: confluent *HEp*-2 cell monolayers in 5·0 cm Petri dishes were inoculated with 0·2 ml. of virus at an appropriate dilution, and adsorption was allowed to proceed at 37° C for 30 min with occasional redistribution of virus-containing fluids. Residual unattached virus was removed without further washing, and 5·0 ml. of fresh growth medium were added to each dish after which incubation at 37° C was continued. Twenty-four hours after virus inoculation, the growth medium was replaced with 3·0 ml. of a chilled suspension of 0·5 per cent chicken erythrocytes in 0·15 M sodium chloride. After the erythrocytes had settled on to the monolayer (this usually required 20 min), unadsorbed red cells were removed by washing the monolayers several times with chilled saline. The haemadsorbing foci could be seen with a dissecting microscope with an opal glass stage at × 10–20 magnification. The appearance of foci under these conditions is shown in Fig. 1. A direct relationship was found to exist between the relative virus concentration and the number of haemadsorption foci (Fig. 2). This suggested that each focus resulted from the action of a single infectious particle. Virus titres were expressed in terms of haemadsorption focal units (HFU), as suggested by Watkins for herpes simplex virus[7].

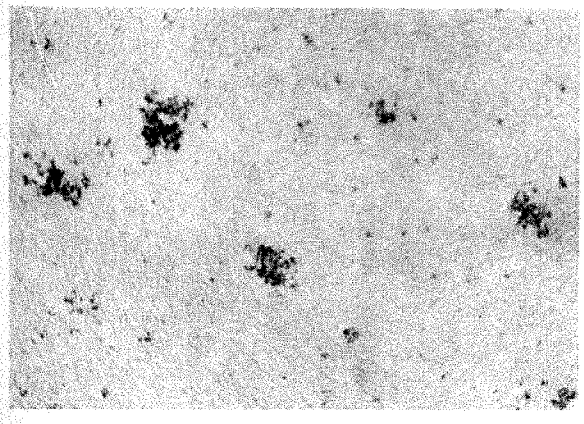

Fig. 1. Haemadsorption foci produced by NDV-infected *HEp*-2 cells (× *c.* 12)

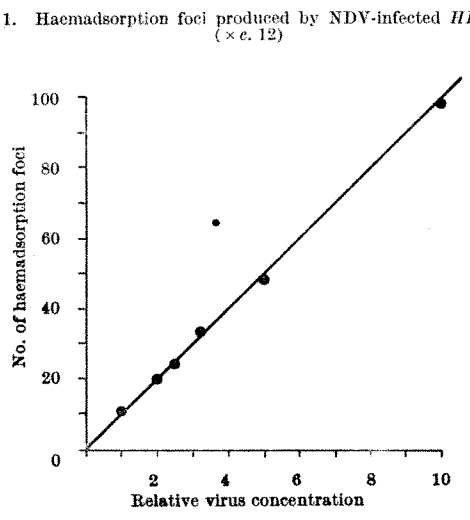

Fig. 2. Relationship between the relative virus concentration and the number of haemadsorption foci appearing in *HEp*-2 cell monolayers 24 h after virus inoculation

The adsorption of the virus to cell monolayers in Petri dishes was measured by the subsequent appearance of haemadsorption foci following various intervals of contact between virus and cells. The adsorption of NDV to *HEp*-2 monolayers was found to be maximal 30–40 min after inoculation and was in good agreement with the findings of Rubin *et al.*[8], who studied the adsorption of NDV to chick embryo cell monolayers.

Experiments with antiserum prepared against the *OS* strain of NDV have shown that *in vitro* incubation of NDV with antiserum for 30 min at 37° C completely abolished the ability of the virus to form haemadsorption foci. The addition of antiserum to the medium bathing infected monolayers during the incubation period also inhibited haemadsorption. Antiserum added for 30 min to monolayers 24 h after virus inoculation (at which time haemadsorption foci were fully developed in control monolayers) resulted in a loss of the erythrocyte-binding capacity of infected cells. Marcus[9] has observed a similar effect with NDV-infected HeLa cells.

The assay system described here offers distinct advantages over previously described methods for quantification of NDV infectivity. The need to maintain embryonated eggs or the preparation of primary chick embryo monolayers is circumvented, as a serially passed line of cells can be used in this assay. Agar overlays, staining and the use of antisera are unnecessary. Perhaps the main advantage of our system is that accurate results are available considerably earlier than they are with conventional plaque assay methods. The properties of this system indicate that it may be of value, not only in experimental studies with NDV, but also in clinical situations where time is an important factor.

SOIL SCIENCE

A Chemical Index of Soil Nitrogen Availability

MANY laboratory methods of obtaining an index of the availability of soil nitrogen to plants have been proposed, but biological procedures involving estimation of the amount of nitrogen mineralized when soil is incubated under aerobic conditions at 28°–35° C for 1–4 weeks have been generally preferred[1]. However, recent work has shown that the results of these incubation procedures are greatly affected by the method and duration of storage of the soil sample before analysis. This has led to a renewal of interest in chemical methods, because it seems likely that the results of chemical methods will be less affected by preliminary handling and storage of the soil

sample than the results of incubation methods. A chemical approach to the problem of obtaining an index of soil nitrogen availability is also encouraged by the experience that chemical methods of analysis are usually simpler and more rapid and precise than biological techniques. Studies in our laboratory of chemical methods of obtaining an index of the availability of soil nitrogen to plants have led to development of the following procedure which appears suitable for routine analysis of soils.

Five grams of < 2 mm soil is placed in a 125-ml. Erlenmeyer flask, 30 ml. of water is added, and the soil–water mixture boiled under reflux for 60 min, using a rheostat-controlled electric hot-plate. Twenty millilitres of 10 per cent (w/v) solution of potassium sulphate is added to the cooled soil–water mixture, the flask swirled for a few seconds to mix the contents, and the mixture filtered under suction (Whatman No. 42 filter paper). A 20-ml. portion of the filtrate is pipetted into a 50-ml. Kjeldahl flask designed for use with the steam distillation apparatus as described by Bremner and Keeney[2], and treated with 2 ml. of concentrated sulphuric acid. The flask is then heated on a micro-Kjeldahl digestion rack until the water has evaporated and the digest is cleared, and digestion is continued for 30 min after clearing. After completion of digestion, the flask is allowed to cool, about 10 ml. of water is added (slowly, and with shaking), and the flask cooled under a cold water tap. Five millilitres of boric acid indicator solution[2] is added to a 50-ml. Erlenmeyer flask marked to indicate a volume of 35 ml., and the flask placed under the condenser of the steam distillation apparatus. The cooled Kjeldahl flask is connected to the distillation apparatus, 10 ml. of 10 N sodium hydroxide placed in the funnel of the apparatus, and the alkali slowly added to the Kjeldahl flask by raising the funnel plug. Steam distillation is initiated by closing the stopcock on the steam bypass tube of the distillation apparatus, and the distillation stopped by opening this stopcock when the distillate has reached the 35 ml. mark on the receiver flask (the rate of distillation is about 7·5 ml./min, and the period of distillation about 4 min). The ammonium–nitrogen in the distillate is then determined by titration with 0·005 N sulphuric acid from a microburette graduated at 0·01 ml. intervals.

The procedure described and other laboratory methods of obtaining an index of soil nitrogen availability were evaluated by applying them to twenty-five surface soils having widely different nitrogen contents and by comparing the results with those obtained in a greenhouse study of the availability of the nitrogen in these soils to ryegrass. The laboratory procedures were applied to soil samples which had been air-dried, crushed to pass a 2 mm sieve, and stored for 2 months in tightly sealed glass bottles. The incubation methods evaluated included the technique described by Bremner[1] which involves an estimation of the (exchangeable ammonium + nitrate + nitrite)-nitrogen produced by incubation of soil under aerobic conditions at 30° C for 14 days, and a modification of the incubation procedure of Waring and Bremner[3], which involves an estimation of the ammonium–nitrogen produced by incubation of soil under waterlogged conditions at 40° C for 7 days (this modification was used because it was found to give better results than the original procedure involving incubation at 30° C for 14 days). The chemical methods evaluated included the alkaline permanganate distillation procedure of Subbiah and Asija[4], the sodium hydroxide microdiffusion method of Cornfield[5], total soil nitrogen as determined by Kjeldahl analysis, and the procedure proposed here.

The relationships between the results of the laboratory methods and nitrogen uptake by ryegrass are given in Table 1. It can be seen that the results of the aerobic and waterlogged incubation methods and of the chemical procedure proposed were more highly related to nitrogen uptake by ryegrass than were the results of the other methods tested.

Table 1. RELATIONSHIPS OF RESULTS OF VARIOUS LABORATORY METHODS AND NITROGEN UPTAKE BY RYEGRASS (TWENTY-FIVE SOILS)

Method	Correlation coefficient (r)*
Incubation	
Aerobic	0·71
Waterlogged	0 73
Chemical:	
Proposed	0 77
Subbiah and Asija	0·43
Cornfield	0 45
Total soil nitrogen	0·52

*$r > 0{\cdot}40$, $P = 0\ 05$; $r > 0{\cdot}51$, $P = 0\ 01$; $r > 0{\cdot}62$, $P = 0{\cdot}001$.

The chemical method described was developed from investigations of a procedure proposed by Livens[6] involving Kjeldahl estimation of the nitrogen extracted from soil by boiling water. We confirmed Livens's finding that his procedure provides a good index of the availability of soil nitrogen, but found that difficulties encountered in filtration of boiling water extracts of soils made this method impractical for routine analysis of soils. The method proposed has the advantages that it requires only a small sample of soil and yields an extract which is readily filtered and analysed. The extracts obtained by this method contain more nitrogen than those obtained by Livens's method, because the procedure adopted extracts exchangeable ammonium as well as nitrate and organic nitrogen. The Kjeldahl technique used for analysis of these extracts recovers the ammonium and organic nitrogen present, but excludes most of the nitrate. Besides being simple and precise (standard deviation, about 1 p.p.m.), the procedure proposed has an important advantage over incubation methods in that its results are not affected by air-drying or by air-dry storage of soil samples before analysis. For example, by this procedure, the averages of the values obtained of the extractable nitrogen for twenty-five soils were 48 p.p.m. using field-moist samples, 49 p.p.m. using freshly air-dried samples, and 43 p.p.m. using samples which had been air-dried and stored for 2 months before analysis.

Unusual Sorption of Caesium by Vermiculite

SEVERAL recent reports[1–5] show that micas and vermiculite exhibit a strong affinity for caesium in dilute solutions. These sorptions, however, have been carried out in the presence of free electrolyte and the quantities sorbed were measured after equilibrium was reached. This communication describes an unusual time course of sorption of caesium by vermiculite in the absence of free electrolyte.

Montana vermiculite was suspended in 1 N sodium chloride solution and stirred in a Waring blender. The suspension was then washed free of excess sodium chloride and the particles smaller than 2μ were separated by sedimentation. Portions of the suspension containing particles smaller than 2μ were saturated with potassium or calcium by five centrifuge washings with 1 N solution of the chloride of the cation. Next excess electrolyte was removed and the colloid was suspended in water. Then, portions containing about 0·1 g vermiculite were withdrawn and centrifuged. The colloid was then suspended in 50 ml. of 10^{-4} N caesium chloride solution labelled with caesium-137. After various periods of time a 3-ml. portion was withdrawn from the mixture, centrifuged and the caesium-137 activity in the supernatant liquid determined by a scintillation counter. The vermiculite used in this

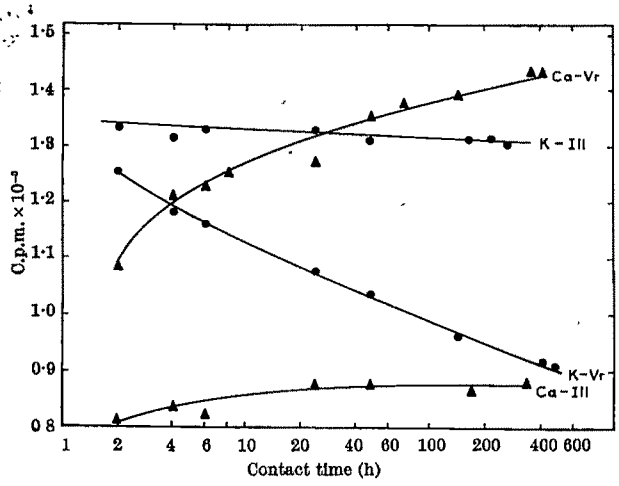

Fig. 1. Sorption of caesium by calcium- or potassium-saturated illite (Ill) and vermiculite (Vr) as a function of time. Caesium sorbed was determined by the difference between the activity of the original and the final solution in contact with the mineral

experiment consisted of about 90 per cent vermiculite and about 10 per cent interstratified vermiculite–biotite and had an exchange capacity of 140 m.equiv./100 g as determined by the method of Sawhney *et al.*[6]. A 2–0·2μ fraction of Fithian illite was similarly treated. Sorbed caesium was calculated from the difference between the activity of the caesium solution added and that of the supernatant liquid.

The results (Fig. 1) show that a slight increase in the amount of caesium sorbed by calcium-saturated illite occurred during the first few hours and it then remained constant, while the amount of caesium sorbed by potassium-saturated illite decreased slightly with time. On the other hand, the amount of caesium sorbed by calcium-saturated vermiculite continued to increase with time, while that sorbed by potassium-saturated vermiculite continued to decrease with time. Caesium sorbed by potassium-saturated vermiculite decreased from 82 per cent of added caesium at the end of 2 h to only 59 per cent at the end of 480 h. Further, in neither vermiculite was equilibrium reached even after 500 h. In contrast to this, when free electrolyte was present, equilibrium was reached in less than 24 h (ref. 1). The decrease in caesium sorbed by potassium-saturated vermiculite occurred at 5°, 25° and 80° C. Experiments showed that small amounts of potassium displaced from clay by caesium did not interfere in the determination of caesium-137 activity.

Attempts were next made to find an explanation for this unusual behaviour of potassium-saturated vermiculite. From the decrease in caesium sorbed with time, it is obvious that a maximum of caesium is sorbed very quickly, perhaps instantly, by a potassium-saturated vermiculite. This may change the mineral lattice so that caesium is extruded out of the interlayer edge sites where it is sorbed from dilute solutions[1].

A possibility suggested by J. A. Kittrick is that if potassium-saturated vermiculite in water is partially expanded by some water molecules in the interlayers, then the sorption of a less hydrated ion, caesium, at the interlayer edges of some crystals would bring the layers closer together. This would increase the attraction between the layers and would collapse the lattice. Since potassium would be the dominant interlayer cation and caesium would be only on the interlayer edges of these platelets, their *c*-axis spacing would be 10 Å. And, since caesium has a larger diameter, it will not fit into the collapsed 10 Å spacing, and thus would be extruded out because of the steric effect.

To test this hypothesis, the *c*-axis spacing of potassium-saturated vermiculite to which 10^{-4} N caesium chloride had been added, and caesium-saturated vermiculite was determined by X-ray diffraction. Portions from above vermiculite suspensions were centrifuged, and the colloid was suspended in minimum water. These thick suspensions were transferred to glass slides and X-rayed when wet, just short of flowing. A 'Norelco' X-ray diffraction unit with a flat specimen holder and a wide-range goniometer was used.

Wet potassium-saturated vermiculite had a 23 Å, a 11·5 Å and a 10 Å spacing; the potassium-saturated vermiculite was, thus, found to be partially expanded. No change was detected in these spacings when 10^{-4} N caesium chloride was added to potassium-saturated vermiculite. This would be expected, since the sample is still saturated primarily with potassium, and only a small fraction of it has caesium on its interlayer edges. On the other hand, wet caesium-saturated vermiculite had a collapsed 10·8 Å *c*-axis spacing as against a 12 Å observed by Barshad[7]. This supports the postulate that the caesium sorption, by a potassium-saturated and partially expanded vermiculite, brings the layers closer and may, thus, increase the attraction between the layers and collapse the lattice.

The results obtained support the hypothesis that caesium, being a larger ion than potassium, is extruded from the potassium-saturated and collapsed 10 Å lattice of vermiculite, and hence a decrease in sorbed caesium is observed.

This investigation was supported in part by a contract with the U.S. Atomic Energy Commission.

GENERAL

"Significant" and "Highly Significant"

THE proposal by Dr. Miller[1] for quantitatively defined terms for various degrees of probability seems to me to be excellent. I would like to suggest, however, that the word "conclusive" for the case where $P < 0{\cdot}001$ is undesirable. The term "conclusive" suggests that no further work need be done and that no alternative interpretation is possible. In fact, an industrious person who does a few thousand experiments on the effects of a similar number of different chemicals on a particular biological process will expect to find a few of these apparently giving effects at the $P < 0{\cdot}001$ level owing to random chance even if none of the chemicals has any real effect at all.

It is almost certain that this occurs from time to time in the pharmaceutical field and little harm is done, at least in informed circles, by the statement that a particular result gives the probability specified, because it will be realized that much work may still be needed before the result can be regarded as genuinely established. If the term "conclusive" were used in the scientific literature at this stage, however, it could have a most undesirable result. When used in the advertising sense to the general public the word "conclusive" really cannot be expected to mean anything except conclusive. The word "decisive", though this case is not quite so serious, does seem also to suffer from the same disadvantage.

J. H. FREMLIN

Department of Physics,
University of Birmingham.

FORTHCOMING EVENTS

(Meetings marked with an asterisk are open to the public)

Thursday, August 25

TELEVISION SOCIETY (in the Conference Suite, I.T.A., 70 Brompton Road, London, S.W.3), at 7 p.m.—Discussion Meeting on "Should Britain have a Single or Dual-Standard Colour Television Service?"

APPOINTMENTS VACANT

APPLICATIONS are invited for the following appointments on or before the dates mentioned:

RADIOCHEMISTRY TECHNICIAN/SENIOR TECHNICIAN (preferably familiar with the techniques of working with radioactive isotopes)—The Director, Scottish Research Reactor Centre, East Kilbride, near Glasgow (August 26).

ASSISTANT EXPERIMENTAL OFFICER, SOIL CHEMIST (with a pass degree in science with chemistry as a major subject, H.N.C. in chemistry or an equivalent qualification) to undertake work involving the analysis of soil and plant materials—The Secretary, Hill Farming Research Organization, 29 Lauder Road, Edinburgh, 9 (August 27).

TEMPORARY LECTURER or TEMPORARY ASSISTANT LECTURER (suitably qualified graduate) IN GEOLOGY IN THE FACULTY OF SCIENCE, to give lectures and practical classes in metamorphic petrology to second- and third-year undergraduates, and to assist with some practical classes in mineralogy and crystallography—The Registrar, The University, Manchester, 13, quoting Ref. 183/66/Na (August 27).

ASSISTANT LECTURER or LECTURER (with a special interest in Eastern Europe (excluding the U.S.S.R.) and some knowledge of an Eastern European language, or prepared to learn one) IN GEOGRAPHY—The Registrar, University of Nottingham, University Park, Nottingham (August 29).

BIOCHEMIST (honours graduate in chemistry or biochemistry) IN THE CHEMICAL PATHOLOGY DEPARTMENT, Queen Elizabeth Hospital for Children, London, E.2—The Group Secretary, Administrative Offices, Hackney Hospital, London, E.9 (August 31).

BIOCHEMIST (with at least an honours B.Sc. in biochemistry, or, if medically qualified, extensive biochemical experience) IN THE DEPARTMENT OF ANATOMY, Queen's College, to join a team of biologists investigating cellular and subcellular effects of high pressure oxygen on organs in culture—The Secretary, University of St. Andrews, Queen's College, Dundee (August 31).

LECTURER IN VETERINARY PARASITOLOGY—The Registrar, The University, Liverpool, quoting Ref. CV/187/N (August 31).

LECTURER or ASSISTANT LECTURER IN PHYSICS—The Registrar, University College of Swansea, Singleton Park, Swansea, South Wales (August 31).

LECTURER or ASSISTANT LECTURER (with a specialized knowledge in physical oceanography, particularly hydrology) IN THE DEPARTMENT OF OCEANOGRAPHY—The Deputy Secretary, The University, Southampton (August 31).

RESEARCH ASSISTANT (with an honours degree in physics or metallurgy and a knowledge of electronics) IN THE DEPARTMENT OF GEOLOGY, to collaborate in continuing electron microprobe studies of minerals with emphasis on solid solution relationships of sulphide, oxide, metal and silicate phases, and to be responsible for the operation and maintenance of microanalytical equipment—The Secretary, University College, Gower Street, London, W.C.1 (August 31).

SENIOR LECTURER/LECTURER IN PHARMACY at Rhodes University, Grahamstown, South Africa—The Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (South Africa and London, August 31).

LECTURER or ASSISTANT LECTURER (with an honours degree in engineering or mathematics and some experience in structural and/or machine vibration problems) in the Institute of Sound and Vibration Research—The Deputy Secretary, The University, Southampton (September 1).

LECTURER or DEMONSTRATOR (with interests in the genetics and biochemistry of micro-organisms) IN THE DEPARTMENT OF GENETICS—Dr. Sydney Smith, Department of Zoology, University of Cambridge, Downing Street, Cambridge (September 1).

LECTURER (with good academic qualifications and postgraduate experience, a special interest in the analysis and design of power generation and distribution systems, and preferably familiarity with modern methods of analysis and simulation of systems using computer techniques) IN ELECTRICAL ENGINEERING—The Registrar, University College of Swansea, Singleton Park, Swansea (September 1).

SHELL-MEX and B.P. LECTURER (with a degree in medicine, physiology, psychology or engineering and experience in some aspect of aeronautical vibration and noise problems) IN THE INSTITUTE OF SOUND AND VIBRATION RESEARCH—The Deputy Secretary, The University, Southampton (September 1).

EXPERIMENTAL OFFICER IN THE DEPARTMENT OF GEOLOGY to act as curator of the teaching and research collections of rocks, minerals and fossils, to be responsible for some museum-type display work, and to supervise the departmental library and map collection—The Registrar, The University, Manchester, 13, quoting Ref. 184/66/Na (September 3).

TUTOR (preferably with a higher qualification in medicine) IN MEDICINE—The Registrar, The University, Manchester, 13, quoting Ref. 188/66 (September 3).

LECTURER or ASSISTANT LECTURER (preferably with interests in either physical or economic geography, particularly of the developing countries) IN THE DEPARTMENT OF GEOGRAPHY, Fourah Bay College, The University College of Sierra Leone—The Inter-University Council, 33 Bedford Place, London, W.C.1 (September 5).

LECTURER (suitably qualified in sociology or social anthropology, with a higher degree and some experience of lecturing or tutoring at the undergraduate level) IN SOCIOLOGY at the University of New England, Armidale, New South Wales, Australia—The Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (Australia and London, September 5).

SUPERINTENDENT (with appropriate qualifications, for example, in veterinary science or pathology) OF THE ANIMAL HOLDING AND BREEDING UNIT, to assist in planning the proposed unit and to supervise it when established—Mr. G. R. Anderson, Assistant Registrary, The Old Schools, Cambridge (September 5).

LECTURER or ASSISTANT LECTURER IN PSYCHOLOGY at Queen's College, Dundee—The Secretary, University of St. Andrews, Queen's College, Dundee (September 8).

ASSISTANT EXPERIMENTAL OFFICER (with O.N.C. in appropriate subjects, or equivalent, or expecting to obtain O.N.C. this summer, and preferably ex-Service candidate) IN THE INDUSTRIAL DIVISION OF THE DEPARTMENT OF INDUSTRIAL AND FORENSIC SCIENCE, Ministry of Commerce—The Secretary, Civil Service Commission, Stormont, Belfast 4, Northern Ireland (September 9).

EXPERIMENTAL OFFICER (Analytical Chemistry) (with an honours degree in chemistry or a qualification in geochemistry) IN THE DEPARTMENT OF GEOLOGY, University of Ibadan, Nigeria, to work in the geochemical laboratory on the chemical analysis of silicate rocks and minerals—The Inter-University Council, 33 Bedford Place, London, W.C.1 (September 9).

VETERINARY PATHOLOGIST (M.R.C.V.S. or its equivalent with postgraduate training and practical experience in veterinary pathology) in the Ministry of Agriculture's Veterinary Research Laboratories, Stormont, Belfast, Northern Ireland, to collaborate in the routine diagnostic and research activities of the laboratories and may be required to undertake lecturing duties in the Faculty of Agriculture in Queen's University—The Secretary, Civil Service Commission, Stormont, Belfast, Northern Ireland (September 9).

LECTURER (graduate in science, already with, or wishing to have, experience and research opportunities in virology including clinical virology) IN THE DEPARTMENT OF BACTERIOLOGY—The Secretary, The University, Aberdeen (September 10).

RESEARCH FELLOW (with a good honours degree or equivalent qualification in engineering or physics) IN THE DEPARTMENT OF ELECTRICAL ENGINEERING for the fundamental study of high voltage power cables including heat transfer and cryogenics—The Deputy Secretary, The University, Southampton (September 10).

UNIVERSITY DEMONSTRATOR (with an honours degree in engineering, agricultural engineering, or appropriate postgraduate training) IN AGRICULTURAL ENGINEERING, to teach and conduct original investigations on farm machinery and implements and their uses—The Secretary, School of Agriculture, University of Cambridge, Downing Street, Cambridge (September 12).

CHAIR OF MATHEMATICAL STATISTICS—The Registrar, University of Liverpool, Liverpool (September 17).

LABORATORY SUPERINTENDENT and ADMINISTRATOR (with experience in administration and preferably a knowledge of laboratory organization and professional qualifications)—Prof. S. V. Perry, Department of Biochemistry, University of Birmingham, Birmingham 15 (September 19).

UNIVERSITY LECTURER (preferably with an interest in experimental taxonomy) IN BOTANY and CURATOR OF THE CLARIDGE DRUCE HERBARIUM—The Administrator, Botany School, University of Oxford, South Parks Road, Oxford (September 20).

EXPERIMENTAL OFFICER/ASSISTANT EXPERIMENTAL OFFICER (candidates over 22 should have a degree in mathematics or physics) IN THE UNIT OF STRUCTURAL CHEMISTRY, to assist with computational aspects of X-ray crystallography—The Secretary, Agricultural Research Council, 15 Regent Street, London, S.W.1 (September 30).

LECTURER (preferably with special interests in physical chemistry) IN CHEMISTRY at the University of Otago, Dunedin, New Zealand—The Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (New Zealand and London, September 30).

LECTURER/SENIOR LECTURER and a LECTURER IN CIVIL ENGINEERING at the University of Sydney, Australia—The Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (Australia and London, September 30).

DIRECTOR OF THE FITZWILLIAM MUSEUM—The Registrary, University Registry, The Old Schools, Cambridge, marking envelope "Confidential" (October 10).

DIRECTOR OF THE NATIONAL INSTITUTE FOR RESEARCH IN DAIRYING—The Secretary, National Institute for Research in Dairying, University of Reading, Shinfield, Reading, Berkshire (October 15).

CHAIR OF GENERAL PHILOSOPHY (History of Philosophy and Systematic Philosophy) IN THE FACULTY OF PHILOSOPHY of the University of Berne, Switzerland—Director of Public Education of the Canton of Berne, Munsterplatz, 3000 Berne, Switzerland (October 31).

ASSISTANT EXPERIMENTAL OFFICER or EXPERIMENTAL OFFICER IN THE DEPARTMENT OF GEOLOGY, for mineral analysis by X-ray spectrometry, to take charge of an analytical service and initiate developments using X-ray fluorescence and electron-microprobe techniques—The Assistant Bursar (Personnel), University of Reading, Reading, Berkshire.

GRADUATE BIOCHEMIST or CHEMIST (wishing to proceed to a higher degree) for research on soluble collagens of the human intervertebral discs, using recently developed chemical and physical techniques—The Registrar, Bradford Institute of Technology, Bradford, 7.

GRADUATE BIOCHEMIST or ORGANIC CHEMIST at the Chester Beatty Research Institute, to assist in research into the nature and consequences of the binding of chemical carcinogens to nucleic acids and proteins in vivo using radioactive techniques—The Secretary, Institute of Cancer Research, Royal Cancer Hospital, 34 Sumner Place, London, S.W.7, quoting Ref. 301/B/261.

HISTOPATHOLOGIST (with a medical or veterinary degree, postgraduate experience in histopathology and preferably general research and/or a specialized knowledge of histochemistry) IN THE DEPARTMENT OF EXPERIMENTAL PATHOLOGY, Chester Beatty Research Institute, Fulham Road, S.W.3—The Secretary, Institute of Cancer Research, Royal Cancer Hospital, 34 Sumner Place, London, S.W.7, quoting Ref. 300/G/25.

LECTURER (with particular interests in transition metal chemistry, and an active interest in research) IN INORGANIC CHEMISTRY—The Registrar, University of Manchester Institute of Science and Technology, Sackville Street, Manchester, 1, marking envelope "Lecturer—Inorganic Chemistry".

PHYSICIST, BASIC GRADE (honours graduate, male or female, in physics) in a newly established medical physics department serving Cornwall and South-West Devon, based in new premises at Plymouth General Hospital—The Hospital Secretary, Plymouth General Hospital, North Friary House, Greenbank Terrace, Plymouth, Devon.

PHYSIOLOGIST/BIO-PHYSICIST to study physiological response to controlled changes in environmental conditions—D. C. Page, Head of Personnel Services, The Electricity Council, Research Centre, Capenhurst, Chester, quoting Ref. N/28.

POSTDOCTORAL RESEARCH FELLOW IN THE DEPARTMENT OF CHEMISTRY for research on solid state Raman spectra, using the new Cary 81 Laser/arc Raman spectrometer, in the general field of inorganic chemistry—Prof. I. R. Beattie, University of Southampton, Southampton.

POSTDOCTORAL RESEARCH FELLOW IN THE DEPARTMENT OF CHEMISTRY, to work with Dr. B. Capon on an investigation of bifunctional catalysis—The Registrar, The University, Leicester.

RESEARCH ASSISTANTS (with a degree, or equivalent, in engineering, and prepared to carry out research in electrical engineering, under guidance) IN THE DEPARTMENT OF ELECTRICAL AND CONTROL ENGINEERING, Liverpool Regional College of Technology, Byron Street, Liverpool, 3—The Director of Education, Education Offices, 14 Sir Thomas Street, Liverpool, 1.

RESEARCH PHYSICIST (preferably with a higher degree and relative experience) IN THE PHYSICS DEPARTMENT, to undertake an investigation of

electron scattering using 400 kV electron diffraction camera with a recently constructed energy analysis facility—The Assistant Bursar (Personnel), University of Reading, Reading, Berkshire.

SPECTROGRAPHIC TECHNICIANS IN THE DEPARTMENT OF MINES AND TECHNICAL SURVEYS, to determine trace elements in rocks, minerals, ores, and related materials of interest to Research Scientists engaged in geological, geochemical and mineralogical studies—The Civil Service Commission of Canada, Ottawa 5, Canada.

TECHNICIAN or SENIOR TECHNICIAN (with a special knowledge of electronic equipment as used in physiology and biochemistry) IN THE DEPARTMENT OF PHYSIOLOGICAL CHEMISTRY—The Acting Bursar (Personnel), University of Reading, Reading, Berkshire.

TECHNICIANS and SENIOR TECHNICIANS IN THE DEPARTMENT OF PHYSIOLOGICAL CHEMISTRY to assist with laboratory classes and to help with research work—The Assistant Bursar (Personnel), University of Reading, Reading, Berkshire.

TECHNICIANS/JUNIOR TECHNICIANS (2) (preferably with experience in sterile techniques and/or tissue culture) IN THE CYTOGENETICS SECTION OF THE NUFFIELD UNIT OF MEDICAL GENETICS, where a study of human chromosomes in relation to abnormal development, including cancer, is being carried out—The Registrar, The University, Liverpool, 3, quoting Ref. 193/N.

TECHNICIAN (student or junior status, preferably with previous experience in immunology, biochemistry or microbiology) IN THE DEPARTMENT OF IMMUNOLOGY, to work on cellular aspects of immunology—The Secretary, The Wright-Fleming Institute of Microbiology, St. Mary's Hospital Medical School, Paddington, London, W.2.

PREPRINTS GALORE

THOSE brave spirits in the United States who would launch a formal scheme for circulating preprints of scientific papers are mostly at fault by being overzealous (see *Nature*, **211**, 333; 1966). But may they not also be unreasonably innocent of practical problems? Certainly the experience of the Information Exchange Groups being run from the National Institutes of Health in the United States, and referred to on page 904 of this issue, should be a stern warning to the would-be managers of the Physics Information Exchange (PIE). The memoranda circulated by Dr. Albritton, who administers the torrents of preprints now flowing in and out of biological laboratories throughout the world, are as clear a proof as anybody could expect that the benefits expected from the information exchange groups are likely to prove illusory.

To say this is not to imply that the IEG system is without value of any kind. On the contrary, as Professor Michael Woodruff has made plain (*Nature*, **211**, 560; 1966), individual scientists can profit greatly from this kind of service. But there are others who find the arrival of bundles of preprints with successive deliveries of mail a far from welcome phenomenon. For one thing, there are frequently too many of them for busy people to be able to digest. And though there is always the chance of coming across something of great value and immediate interest, the depressing truth is that the gold is accompanied by a great bulk of unwanted dross. One result is that some members of the Information Exchange Groups have decided they can afford to wait until research reports eventually appear in print. Really hot news, after all, has its own ways of getting into circulation. (It will be fascinating to see how long it is before authors start circulating to colleagues who are particularly concerned documents which will no doubt be known as pre-preprints.) The usefulness of the IEG system is bound, of course, to vary from one field to another, and even from one laboratory to another, but that is only to be expected. It is nevertheless worth recording simply because the sponsors of these print systems always suppose that what they have to offer will be of unalloyed benefit at least to those who are recipients—as distinct from providers—of information. Even that assumption is not as safe as it may seem at first sight.

None of this, however, is a good reason for complaining at the magnanimity of the National Institutes of Health. If the IEG system were simply an adjunct to the existing means of communication between professional scientists, it would not matter if some of those on the mailing lists found their presence there of little value. But things are not, unfortunately, as simple as this. The IEG scheme, like the PIE that may follow, is not a part of the world's natural resources which can be used or ignored as circumstances suggest. For one thing, it involves the deliberate spending of substantial sums of money, so that it is proper and indeed essential to ask whether the same resources might not be spent more profitably in other ways. But these schemes are also important—and suspect—because, if they continue, they cannot fail to have an important influence on the character of the scientific literature and, therefore, on the character of science itself.

There is enough in Dr. Albritton's memoranda to show that the cost of organized preprint circulation may be very much more than has previously been calculated. He estimates that the cost of a fully developed system would be $5 million a year, though that is probably an optimistic calculation. The cost of the IEG circulation is at present thought to be roughly $100 for each member—or enough to supply each of them with several free subscriptions to orthodox journals. Is the benefit really worth that cost? And if the National Institutes of Health are really anxious to help the flow of information between scientists, might they not do better by helping to provide some of the common services that could make the orthodox channels of communication more efficient, more effective, and more speedy? Questions like these have received only the most cursory attention, no doubt because they are difficult to answer. But to flood the world with preprints is the most facile of all solutions.

The effects of the preprint circulation schemes on the balance of the literature as a whole can be inferred without too much difficulty from Dr. Albritton's breezy account of the practical problems of preprint circulation. The fact that the delay in what is called the "print-shop" can be as much as two months, with an extra month or so for those who do not type their manuscripts properly, will not surprise the organizers of conventional journals. There is no doubt a Parkinsonian law to the effect that the demand by those with something to say on any uncontrolled channel of communication is certain to increase to the point of saturation. The difficulty, of course, is that IEG cannot take steps to choke off the demand without violating the basic principle that it must be indiscriminate and undiscriminating. (Even so, it would surely have been well within the spirit of the law if Dr. Albritton had restrained himself from issuing his tactless document with the slogan "Why not send it to us NOW?") The truth is, of course, that there is a sharp and irreconcilable conflict between the laudable wish of the preprint circulators to have everybody on their mailing lists, and their fond pretence that they are not engaged in the publication business. No amount of fine print among the rules of membership can alter that. So long as the circulation of preprints is sufficiently wide, within the scientific community, for scientists to be able to claim priority for their discoveries—and to make fools of themselves as well—then the system has all the properties of a channel of publication, and is intended to have them. Its defects are inaccessibility,

impermanence, illiteracy, uneven quality, and lack of considered judgment. Preprint publication differs from the more conventional kind, however, in that authors expect to publish twice, and that disputes over issues such as priority must be settled by reference to the chairman of the group concerned, and not by looking in the library. It would be good to know how the IEG chairmen would seek to deal with offenders who claim that they habitually throw their preprints away. It is proper to record that PIE is potentially more dangerous than IEG, because the names of those with access to the system would not be known to the organizers. It is probable that both systems, in their present forms, are more of a threat to the continuing health of scientific research than a fair wind in its favour.

But if not preprints, then what? The defects of IEG and PIE are no excuse for hiding from the problems which stimulated their emergence. One of these is the speed—or lack of speed—which attends publication in the orthodox journals. It is entirely proper that scientists should wish to see their work published as quickly as possible. The wish to establish priority is, or should be, only a small part of the reason for asking that publication should not be long delayed. It is much more important that the exchange of ideas is an essential part of science, and that the rapid exchange of ideas makes science more alive. Obviously there is a lot which orthodox journals should and could do to make publication faster, by better organization, the use of new printing processes and even of the telephone. Any way in which computers and data processing systems can help to make the literature more manageable and more accessible is obviously a deserving cause. It would be entirely in order if the institutions in the United States now being asked to lavish support on preprint circulation were to spend a fraction of the sum required on helping the journals to become more efficient.

There remain a number of nasty qualitative problems. Journals seek to be discriminating, and in part their reputations depend on how well they succeed. There is evidence that, in the past, the influence of the continuing criticism by the journals of what is eventually published in the literature has itself been an important formative influence in science. It has encouraged thoroughness and measured judgment. It has discouraged triviality and repetitive work. But the question now arises of whether the literature is not ripe for some much more drastic transformation. Much of it is hard to read. Much of it is less effective a means of communicating ideas and information than it could and should be. And, of course, there is too much of it. These characteristics of the existing arrangements for publication need careful attention by the scientific professions as a whole. If the National Institutes of Health are as well disposed towards the cause of effective publication as they seem to be, they could do a lot to help. The energy they choose to dissipate in Dr. Albritton's print-shop will be much less valuable.

CENTRES OF EXCELLENCE

OLD soldiers never die, and it is much the same with laboratories. Professors Richard Post and Marshall Rosenbluth, two members of the University of California, have drawn attention to an interesting and important problem by speaking out in defence of the Culham Laboratory they have been visiting in Britain. Quite properly, they say that the laboratory is a splendid place "unexcelled in the world". They go on to hope that the kind of basic research carried out at Culham will not be restricted as a result of the British Government's wish to use its substantial effort in research and development as a means of helping the economy move forward faster. What they do not say is that the Culham Laboratory was formed at a time when there were fond hopes of turning thermonuclear research to most spectacular practical results, and that its present concern for more academic work —which includes the development of the first ESRO satellite at a cost of £3 million pounds—reflects the recognition there has been that plasma physics is not child's play. The laboratory has done well to survive, let alone to become a centre of excellence.

It remains a real question to ask how Britain should make full use of Culham and of other laboratories which pursue academic—in the sense of uncommercial —ends but which are not incorporated into universities. Professors Post and Rosenbluth are probably right in saying that too crude an attempt to divert academically minded men into other pursuits would persuade a great many of them to emigrate, but in itself that is not an overwhelming argument. If the British Government is persuaded that academic plasma physicists contribute nothing to the economy, in its present mood it would probably be glad to say goodbye to those who do not wish to change their ways. The difficulty, and the real cause for anxiety, is that activities which seem purposeless on a short time-scale can be enormously important in the long run. This is where too crude a decision could be dangerous and there is a possibility that, in its anxiety to balance the books, the British Government will make the pendulum swing too far against research as such.

It is inevitable that laboratories such as Culham will be the first to feel this pressure. It will be interesting to see how they stand up to it. Trying to define how the investment made in them may eventually be returned should be a healthy exercise. To argue that a pool of skill must be maintained is sensible, the not overwhelming by itself. (Undertaking contract work for ESRO, in which Britain is the principal partner, is not a convincing reason for survival.) The ideal would be if these laboratories could find some way of being much more closely integrated with universities, for then they would be able to claim with justice that their activities were at least helpful in educating students. The schemes which exist for taking postgraduate students at these public laboratories are not a sufficient answer to this need.

NEWS AND VIEWS

Public Exploitation

BRITAIN'S National Research and Development Corporation expects to be committed up to its present borrowing limit of £25 million by 1968, according to the annual report for 1965–1966 published last week. The Managing Director, Mr. J. D. Duckworth, is hopeful, however, that Parliament will extend this limit by another £25 million. "If we don't get more," he said, "we must start cutting back on our commitments quite soon until our present investments start paying back." Despite the Government's decision to decrease research expenditure, Mr. Duckworth does not feel that the present financial difficulties will affect the position of this corporation; the sums involved are relatively small and would be invested in development and industrial application, not research. "It is in our area that Britain's economic future depends", he added. Informal discussions take place continually between the NRDC and the Ministry of Technology, but more formal negotiations with the Minister will probably begin in the near future so that a new Act can be presented to Parliament during the next session.

The NRDC was established under the Development of Inventions Act of 1948 to develop inventions derived from publicly supported research and inventions from other sources which lack a sponsor. The original Act was amended in 1954, 1958 and 1965; the 1965 Act increased the borrowing powers of the NRDC from £10 to £25 million. The corporation is designed to act as a link between research and industry, but is increasingly participating in joint ventures with industries both to speed up development of important innovations and to spread the cost of taking risks. Within the past year it has also tried to encourage innovation by sharing risks with the user as well as the developer of new products, although the NRDC only provides some capital and is repayed if profitability or productivity increases. Mr. Duckworth stated that at present only 10 per cent of the corporation's funds are being used in this new venture, but he expects that the proportion will greatly increase in the near future.

The increased activity of the NRDC is shown in the figure of £865,000 for receipts in the nine months to the end of March from licensing, dividends, sale of equipment, and development levies. Nearly £4 million has been spent, and of this more than £3 million on projects. In 1965 the total spent on projects was a mere £500,000.

During the last nine months the NRDC has taken on twenty-eight new projects, bringing its total to 121; 155 others are at present under consideration. The corporation continues to support hovercraft development and is supporting a hoverferry, the *CC6*, being developed by Britten–Norman, Ltd. This is designed to carry four to five cars and between thirty and forty passengers. Support for fuel cells, started in 1953, continues. According to Mr. Duckworth, the cells are not yet economically feasible, but the United States is interested and American licences have led to an exchange of information that should strengthen the technical position of the British effort.

New projects include the development of synthetic insecticides related to natural pyrethrum, which combine the lack of toxicity of the natural pyrethrins with significantly lower costs. There is a metal polish additive which may be useful in making such metals as copper, zinc, steel and aluminium more resistant to tarnishing. NRDC is also supporting projects in such areas as teaching machines, minimal farm cultivation, and a multi-gas burner, and is anxious to support computer-controlled automation studies.

Culham Despondent

Two visiting scientists at Culham Laboratory of the United Kingdom Atomic Energy Authority are pessimistic about its economic future. The two American physicists, Prof. Marshall Rosenbluth of the University of California and Prof. Richard Post of the Lawrence Radiation Laboratory, in a letter to the London *Times* on August 23, stated that they have "heard rumours that due to the present financial crisis, scientific research activities not involving an immediate financial return may be curtailed in Britain". They go on specifically to praise the Culham Laboratory as unexcelled in the field of plasma physics. "A laboratory such as Culham is a precious national asset, difficult to come by".

Prof. Rosenbluth has said on the telephone that Culham scientists are more worried about money than they have been during his frequent visits in the past, but added that he has no specific knowledge to justify his pessimism or that of his colleagues at the laboratory. However, he and Prof. Post state that if there is a cut-back on research funds, they "believe the majority of the creative leaders would be inclined to join the 'brain drain' and come to the United States".

The Ministry of Technology was not prepared to comment on the general situation of government aid for research which is closely tied to the economic situation in Britain as a whole; it does admit, however, that generally it is becoming more difficult to get money. The UKAEA, the public corporation directly responsible for Culham, says that it, like other public organizations, had been asked to save £2 million pounds in the next year, but that as yet no decisions had been taken as to where these cuts should be made. While it was very possible that some cuts would be made at Culham, there was no general policy to reduce the proportion spent on basic research.

Earthquake in Turkey

ON Friday, August 19, 1966, an earthquake of approximate intensity 9 on the Modified Mercalli Scale occurred in Eastern Turkey from an epicentre near latitude 39⅓° N., longitude 41½° E., between Varto and Hinis in Mus Province. This is some 50 miles south-south-east of Erzerum and between Erzerum and the western end of Lake Van. The area is remote and mountainous, and it is believed that more than 2,000 people died and that many more were injured. The shock was felt in the Soviet Union. Aftershocks are continuing and at least one of these was felt as far west as Istanbul, though no damage was done there.

Turkey is a country of which every part is liable to earthquakes, the most stable area being just inland, near the centre of the south coast (in Asia Minor).

The earthquakes have their foci at depths ranging from the surface to some 100 km, though normally the depth is about 13 km. The deeper foci lie roughly on an east–west line starting from near the centre of the west coast of Turkey-in-Asia. The shocks vary greatly in magnitude; there are about eight shocks a year of magnitude 5 or greater on the Richter logarithmic scale. The earthquakes often begin from old foci, occasionally from new ones, and many of these are not near towns. An earthquake at Erzincan on December 26–27, 1939, killed 23,148 people and injured 8,029. 16,629 buildings were completely destroyed (see *Nature*, **145**, 13; 1940).

Most Turkish earthquakes are of tectonic origin, due to "Alpine" orogenic pressure. Slipping occurs when this pressure exceeds that required for movement, usually along one or more of the deep ancient geological faults which abound. The first point which yields becomes an earthquake focus. One such structural line runs through Mürefte, Izmit, Bolu and Gerede, and, although it is a line of earthquake epicentres, it also has such an influence on relief that it is both a very densely populated zone and a corridor for communications. Two other active faults are the Kayas and Akpinar faults.

The general geological structure of Turkey awaits clarification. Three ideas at present hold the arena: (*a*) that it merely consists of strong transverse anticlines and synclines, sometimes faulted along the edges; (*b*) that it consists of a "*Zwischengebirge*" between the Pontine and Taurus Mountains; (*c*) that at Kirsehir is a Pontine nappe and that the Anatolian thrust at its base is essentially a boundary between the Pontic (Black Sea) and Taurus (Mediterranean) pre-Tertiary rocks which differ in facies.

On account of the enhanced interest at the University of Istanbul, Turkey is now better provided with seismograph stations than formally, and some advanced seismological work is being undertaken. N. Canitez and S. B. Ucer have recently recomputed all Turkish epicentres between January 1947 and December 1959, using a digital computer. The accuracies of the new epicentres and times of origin are about $\pm 0{\cdot}1$ degrees and 1·0 seconds respectively. P_n arrivals at epicentral distances less than 16° were used, together with an iteration method which used the local velocity of P_n waves. The standard deviation in both latitude and longitude for the new epicentres is less than $\pm 0{\cdot}1$ degree. The same authors have also investigated the mechanism of some seventy earthquakes which occurred in or near Turkey between the years 1936 and 1965.

Help with Computers

THE Ministry of Technology is continuing to support the development in Britain of new computer techniques. It has just announced that, under its Advanced Computer Techniques Project, twenty-one new contracts worth more than £1 million, and supported jointly by the Government and industry, have been placed in the past year. The Government has also allocated an additional £600,000 for new contracts which are expected to be placed by April 1967.

The project was started under the Department of Scientific and Industrial Research in 1963, when the then government considered there was not enough research and development to maintain a viable competitive position in the world computer market. Seven contracts costing about £325,000 have been completed so far. The ministry's aim is to support projects which are too uncertain or too long term to commend themselves to industry, but which lie in areas that must be developed if the industry is to grow.

The prevailing view is that research and development are chiefly required in the development of fast storage devices, the design of systems and in the working out of a cheap and reliable technology of peripheral equipment and software.

Fresh Fish to Eat

THE report for 1965 of the Director of the Torry Research Station (H.M.S.O., 5*s*. 6*d*.) lays greatest stress on the need for technical innovation in the British fishing industry. The traditional fishing grounds are yielding fewer fish of the types most appreciated by the British public—cod, haddock, plaice and herring—so that the station's development of methods which minimize wastage of fish between catching and consumption is of particular importance. Superchilling of fish in liquid air, pre-packaging wet fish and dip coating of fish in liquids which produce a flexible surface film are methods which have been tried. Another possibility is to fillet the fish before freezing at sea in order to eliminate thawing and refreezing of fish for filleting to be carried out.

Even if spoilage of fish is minimized, however, it seems unlikely that all needs can be satisfied without the introduction of hitherto unexploited species such as redfish, dogfish, saithe and mackerel. These fish could be marketed in traditional ways or as components of made-up products such as fish sausages or fish cakes. A further possibility is to extend the fishing grounds to the South Atlantic, and work has been done on the preservation of fish at higher ambient temperatures in preparation for such a development.

Since these problems are essentially of a practical nature, a shift in the emphasis of the station's work away from basic research has occurred, and will be encouraged. Basic research work, however, still makes up a considerable proportion of the station's effort, and bacteriological and biochemical investigations have continued to be carried out.

Microbiologists in Moscow

AT the end of July over five thousand microbiologists from nearly fifty countries assembled at Moscow State University for their ninth quatrennial congress. More than 1,500 papers were presented or made open for discussion and they covered most aspects of microbiology. Statistics such as these immediately raise the obvious question of the usefulness of this kind of meeting (writes one of the participants). Indeed, the poor standard of many of the communications was such that one would have wished for a more thorough selection in the preparation of the programme. Be that as it may, a great deal of interest emerged during the course of the congress which afforded—and which, through the agency of its published proceedings, will continue to afford—an ideal opportunity for microbiologists to survey their rapidly expanding subject.

One of the undoubted consequences of this huge meeting was the chance of informal discussion with colleagues, and a recurrent theme in these exchanges,

particularly as expressed by Soviet and other scientists from the Soviet Union and from Eastern Europe, was the applicability of microbiological discoveries to industry and agriculture. Several sessions were concerned with applied aspects; and discussions of the automatic control of microbiological processes, and of the engineering equipment required, attracted much attention. Developments in this area of microbiology in the next few years will be rapid and far-reaching. The fuller exploitation of micro-organisms in the production of vaccines, antibiotics and a vast array of organic materials, as well as the problem of producing more food, are of the greatest importance. It was clear from the views expressed in Moscow that the increasing contributions of industries based on microbiology hold promise for the future.

Important information on the complex interactions between microbes and their hosts is coming from what is called gnotobiology — investigation with organisms free from germs or specifically inoculated. These are uniquely useful in the study of physiological processes and diseases in the absence of a microbial vector. With the advent of commercially available animals free from germs, and the isolator chambers for keeping them like that, gnotobiology is advancing rapidly. Included in the programme at Moscow was the use of germ-free techniques in the care of patients, which can be critical for those with impaired immunity mechanisms, as well as in containing contagious diseases in hospitals.

The gnotobiotic implications of space travel were also discussed. During long space flights there may be a high probability of a lethal simplification of the gut flora and the cross-contamination of pathogens. This less publicized problem of space exploration is of great practical significance to the technologist.

Apart from presenting a comprehensive report of the contemporary scene, an international meeting of this nature must also look to the future. To a gratifying extent the organizers of the Moscow congress were successful in establishing this balance which, considering the great diversity of subject matter embraced by microbiology, was no small achievement.

Population Excursions

THE birth rate is still falling steadily in Britain, according to the provisional figures for the June quarter recently issued by the Registrar General; it is estimated that there were 215,000 live births during the quarter, giving a rate of 17·9 per thousand population compared with rates of 18·5 and 19·2 for the corresponding quarters of 1964 and 1965. At the same time, the infant mortality rate has remained low—18·2 per thousand live births is estimated for the second quarter, versus the 1965 average of 19 per thousand. Only Sweden and the Netherlands have appreciably lower rates, while the United States averaged 25 deaths per thousand live births in 1965.

The birth rate may be falling but it is still well above the mortality rate; the Registrar General's Quarterly Return for the March quarter of 1966 reports that there were 862,290 live births in 1965 and only 549,379 deaths, of which 24,254 were from violent causes. The most prolific killer is still coronary and arteriosclerotic heart disease; it accounted for more than a fifth of all deaths in 1965 and at 113,451 is the highest number recorded. In the past 10 years, deaths from this cause have increased by 50 per cent. However, the number of deaths from myocardial degeneration has been steadily declining and reached a record low last year of 38,267. The other three main causes of death were pneumonia, bronchitis and stroke—the first two accounted for 60,595 deaths, and the latter for 78,149. Compared with these figures, the number of violent deaths seems quite small and is the lowest figure in 3 years; accidents involving motor vehicles caused 7,515 deaths, which is an increase in the past 2 years. The most publicized causes of all—murder and war—were responsible for only 317 deaths.

For the future, the Registrar General estimates that the population of the United Kingdom will have increased by 7·0 million by 1981, and that nearly all this increase will have occurred in England. The largest growth is expected to be in East Anglia, the Midlands and south-west England, with percentage increases of 30, 20 and 17 respectively; south-east England, at present containing 35·5 per cent of the English population, is expected to grow at only 12 per cent over the period, or less quickly than the national average.

Respiration Physiology

DR. PHILIP HUGE-JONES writes: The scientific publication explosion is becoming a threat to the assimilation of knowledge almost as alarming as the population explosion to the assimilation of food. So it is now no longer possible to welcome a new journal, as it was a few decades ago, without first assessing the need for its existence. The first number of *Respiration Physiology* has just been published this year with an eminent international editorial board and two distinguished physiologists as editors—Pierre Dejours of Paris as the day-to-day editor and Wallace Fenn of Rochester New York as honorary editor. Is there need for such a journal?

It is interesting to reflect on where articles about respiratory physiology, published in English, have hitherto appeared. In Britain the obvious place has been the *Journal of Physiology*, but with the outstanding success and interest in neuro-muscular physiology in Britain during the past decades, the proportion of articles in that journal about the physiology of respiration has declined. Thus a rough analysis of the contents of the *Journal of Physiology* for 1925 compared with 1965 showed the following percentages: in 1925, neuro-muscular articles 22 per cent, cardio-respiratory 28 per cent, endocrine 28 per cent, other 22 per cent, compared with 1965, neuro-muscular 53 per cent, cardio-respiratory 13 per cent, endocrine 15 per cent, other 19 per cent. During the period the total size of the journal increased from 46 articles to 201; the number of neuro-muscular articles increased from 10 to 106 while those on cardio-respiratory subjects increased only from 13 to 26.

It might seem that in Britain interest has shifted away from human and mammalian respiratory physiology (so ably pioneered here by Haldane, Barcroft, Hill and others) towards neuro-physiology after the success of Sherington, Adrian, and others who have followed the Oxford and Cambridge Schools. In fact, with the decline in interest in respiration among British physiologists there has been a marked increase

in interest among clinical research workers. Some of this applied and clinical respiratory physiology has been published in journals such as *Clinical Science*, but much has been published in the United States. There the *Journal of Applied Physiology* has increased, not only in absolute size but in the proportion of its articles on respiratory physiology, so that the number in March 1966 was a mammoth volume weighing 2·75 lb. and having no less than forty-six articles in it on respiratory physiology out of a total of about seventy. Obviously, there is a demand for space to publish articles about applied respiratory physiology.

What are the credentials of the new journal *Respiration Physiology*? First, it is an international journal in English. Secondly, it seems to aim to bring together the different fields of respiratory physiology from cellular respiration, through comparative respiratory physiology in animals, to applied clinical physiology of man. Unlike the *Journal of Applied Physiology* it is a speciality journal for respiration physiology—as its name implies.

In the first number of *Respiration Physiology* there are nine papers of original research including articles on a theoretical analysis of aquatic gas exchange, experimental work on respiration in an elasmobranch fish, chemical control of breathing in rats, on the pressure flow characteristics of isolated dog's lungs, on temperature and respiration on sleep, and articles on human breathing including gaseous diffusion on the airways, the effects of posture on compliance, on chemoreceptor block and on the determination of carbon monoxide transfer—a wide variety within the speciality of respiration by authors from the United States, Britain, Germany and New Zealand. If this journal can maintain the high standard of contents and layout of its first number it should surely succeed.

Information Exchange

SOVIET scientific and technical information specialists have just completed a three-week tour of Britain, visiting institutions and organizations concerned with storage, dissemination and retrieval of scientific and technical information. A similar visit to the Soviet Union was made by a team of British information specialists in May 1963. The tour was organized by the International Scientific Relations Division of the Department of Education and Science in Britain. The nine delegates, led by Mr. N. B. Arutynov, head of the Directorate of Scientific and Technical Information, State Committee for Science and Technology, Moscow, visited twenty government and industrial libraries and research establishments.

Appointments

DR. J. B. ADAMS, director of the Culham Laboratory, has been appointed a full-time member of the United Kingdom Atomic Energy Authority for 5 years as from October 1.

MR. G. J. BELL has been appointed director of the Royal Observatory, Hong Kong, in succession to Dr. I. E. M. Watts, who has been appointed to the headquarters of the World Meteorological Organization in Geneva.

PROF. D. J. FINNEY, professor of statistics in the University of Edinburgh, and Mr. J. K. Steward, head of the Mathematics and Computer Department of Imperial Chemical Industries, Ltd., have been appointed to the Computer Board. These appointments complete the membership of the board, the establishment of which was announced in the House of Commons on August 3.

PROF. I. S. ZHELUDEV has been appointed deputy director general of the International Atomic Energy Agency for the Department of Technical Operations, in succession to Prof. G. A. Yagodin.

Announcements

THE Culham Laboratory of the U.K. Atomic Energy Authority is to be awarded a contract worth roughly £3 million by the European Space Research Organization (ESRO). The authority will be the principal contractor in the development and construction of the first of the three satellites now included in the ESRO programme. This will be largely concerned with astronomical work. The intention is to launch a 30-in. Cassegrain telescope working in conjunction with a spectroscope working in the ultra-violet between 900 Å and 3300 Å. It is hoped that the alignment of the telescope will be accurate to within one-tenth of a second of arc. The entire payload will weigh 500 lb. and the entire package will be 10 ft. long and 40 in. wide. The present plan is that the satellite will be launched in 1971 using the ELDO launcher for getting off the ground.

FOUR new coastal surveying ships, designed to operate in any part of the world independently for long periods, have been ordered by the British Royal Navy. The new ships, being built by Brooke Marine, Ltd., of Lowestoft, will replace the four converted *Bay* class frigates which have been in service since 1950. When they are completed, the Royal Navy's surveying fleet will consist of four ocean survey ships, four coastal survey ships and seven smaller boats.

THE Canadian Society for Chemical Engineering has been formed within and as a part of the Chemical Institute of Canada. The new society will represent the institute in the field of chemical engineering, both nationally and internationally. The society's first officers are those of the institute's former Chemical Engineering Division, now replaced by the new society, and are: *President*, Dr. D. B. Robinson, chairman of the Department of Chemical and Petroleum Engineering in the University of Alberta; *Vice-President*, Dr. W. H. Gauvin, director of the Noranda Research Centre, Pointe Claire, Quebec; *Secretary-Treasurer*, Dr. N. E. Cooke, Engineering Department, CIL, Montreal. The new society's first annual meeting will take place during the sixteenth Canadian Chemical Engineering Conference which it is sponsoring in Windsor, Ontario, during October 17–19.

THE Harkness Fellowships of the Commonwealth Fund of New York are offered each year for study and travel in the United States. Candidates must be citizens of the United Kingdom or a present British Colony, and must be between the ages of 21 and 32. Further information can be obtained from the Warden, Harkness House, 38 Upper Brook Street, London, W.1.

A JOINT meeting of the Biological Engineering Society and Stichting voor Biofysica will be held at Utrecht during September 22–24. Further information can be obtained from W. J. Perkins, The National Institute for Medical Research, Mill Hill, London, N.W.7.

A CONFERENCE on "Advances in Electron Microscopy", arranged by the Electron Microscopy and Analysis Group of the Institute of Physics and the Physical Society and the Electron Microscopy Section of the Royal Microscopical Society, is being held at the Institution of Electrical Engineers during September 26–28. Further information can be obtained from the Meetings Officer, the Institute of Physics and the Physical Society, 47 Belgrave Square, London, S.W.1.

THE third field meeting of the North of England Soils Discussion Group is being held at Merlewood Research Station, Grange-over-Sands, Lancashire, and in the Morecambe Bay area, during September 26–28. Further information can be obtained from H. T. Davies, National Agricultural Advisory Service, Yorks and Lancs Region, Government Buildings, Lawnswood, Leeds, 16.

THE ninth International Cancer Congress will be held, under the auspices of the International Union against Cancer, in Tokyo during October 23–29. Further information can be obtained from the National Organizing Committee, Ninth International Cancer Congress, c/o Cancer Institute, Nishisugamo, Toshima-ku, Tokyo.

A CONFERENCE on "Electron Nuclear Hyperfine Interactions in Spectroscopy" will be held in Wellington during October 17–21. Further information can be obtained from Dr. R. M. Golding, Conference Secretary, Royal Society of New Zealand, c/o Chemistry Division, D.S.I.R., Private Bag, Petone, Wellington.

THE sixteenth Canadian Chemical Engineering Conference of the Chemical Institute of Canada will be held in Windsor, Ontario, during October 17–19. Further information can be obtained from Dr. P. M. Reilly, Polymer Corporation, Ltd., Sarnia, Ontario.

THE sectional meeting of the World Power Conference, the theme of which is "Problems of Future Years in Energy-Utilization", will be held in Tokyo during October 16–20. Further information can be obtained from the Japanese National Committee, World Power Conference, c/o Japan Power Association, Daido Building, 1–46 Shiba Minamisakuma-cho, Minato-ku, Tokyo.

A SYMPOSIUM on the "Optimization of Chemical Processes", organized by the Royal Institute of Chemistry and the Society of Chemical Industry, will be held at the University of Manchester on October 12. Further information can be obtained from Mr. L. Winestone, Geigy (U.K.), Ltd., Tenax Road, Trafford Park, Manchester 17.

A CONFERENCE on "Engineering of the Future in the Rubber Industry" will be held at Royal Leamington Spa during October 6–7. Further information can be obtained from Mr. A. L. Smith, Controller of Development Compounding, Tyre Compounds Laboratory, Dunlop Rubber Co., Ltd., Fort Dunlop, Birmingham 24.

THE sixth International Congress of Clinical Pathology will be held in Rome during October 3–8. Further information can be obtained from Segreteria del VI Congresso Internazionale di Patologia Clinica, Via dei Penitenzieri 13, Rome.

CORRESPONDENCE

We Wuz Robbed

SIR,—If the object of the World Cup series were to determine the identity of the best playing team, your editorial comment would be justified. But in fact its object, albeit inexplicit, is something much more sophisticated—the generation, abreaction and (one must hope) the control of aggressions in a ritualized form. Because we badly need an emotional technology of this kind I for one would be sorry to see it reshaped, unless it were in the direction of making the therapeutic acting-out more effective. For the operation to succeed, there must be a climatic final contest, there must be built-in uncertainties and unfairnesses (otherwise nobody would have the opportunity of being robbed in a context which does not generate military spirit), and there must be a referee to respect or blame: possibly the ritual would be more effective if, symbolically at least, he were eventually killed and eaten, but the present system is an insightful compromise.

The selection of the "best" team is accordingly a pretext for an important anthropological manoeuvre. That this manoeuvre has grown intuitively rather than as the result of planning adds to its effectiveness, and is typical of a rite. It is an inexpensive project compared with, say, the literal enactment of the shamanic enterprise of Moon travel, and with the restraint imposed by sportsmanship, however variously interpreted, I think it is beneficial. We have too few safe outlets for aggression, rivalry and boasting. We should not let scientism disturb those which we have.

I am, Sir, etc.,

ALEX COMFORT

Department of Zoology,
University College,
London.

Drop More Names

SIR,—I am a regular user of *Science Citation Index* (S.C.I.) and wish to comment on your recent remarks about it (*Nature*, August 6, 1966) because I suspect that you have not used the *Index* for its proper purpose, which is to search the literature for references pertaining to a current scientific problem.

Your description of the principle on which the Index is compiled is correct, but your statement of the fundamental idea behind S.C.I. and your implication that the use of S.C.I. is limited to the pursuit of this idea in any particular case appear to me superficial. In my view S.C.I. enables one to answer the questions: "Has it been done? Has it been thought of? Has it been criticized, proved, or disproved?" S.C.I. permits the questioner to exploit fully his own intelligence and experience in his analysis of the literature without having to rely on the arbitrary choice and use of key-words by abstracters. An abstracter might neglect minor points which later become of major importance to someone else and might even misunderstand a paper.

The following example illustrates the way in which citations found in S.C.I. act as the "labels" by which "ideas" in the literature can be traced. A researcher planning an experiment to distinguish between certain hypotheses considers the range of possible results and their bearing on his hypotheses. Even at this stage he can make a list of the key papers to which he thinks he would have to refer when finally writing his own paper on this research, choosing this list so that it characterizes as many as possible of the aspects of his research. He now finds the citations of his listed papers in S.C.I. Publications which cite two or more papers from his list are likely to be useful. Many of those which cite only one can quickly be dismissed as irrelevant on the basis of their authorship, or the journals in which they appear, or their titles (which are found in the *source index*). If there are no relevant citations, the research worker's idea is probably new.

My experience suggests that literature problems can be solved with S.C.I., within an hour or two of raising them, more completely and quickly than with conventional abstracts. Your alternative suggestion of search by computer is open to the objection that those with the most to learn, undergraduates and graduate students, might not have rapid access to the computer service. Furthermore, although computers are quick, a citation service by computer would suffer from delays in booking time and in supplying in the correct form the information required for a search. The questioner would probably want to alter this information on seeing the results of the search, whereas the individual user of S.C.I. can modify his search procedure as he goes, according to his findings.

Yours faithfully,

MARTIN DAVIES

Harvard Medical School,
Boston, Massachusetts.

FOUR YEARS OF INFORMATION EXCHANGE

THE National Institutes of Health in the United States have for four years been running a rapidly growing system for the exchange of preprints between scientists working in biological fields. The first information exchange group, started in April 1961 on an informal basis, has now been joined by six other groups. The speed with which these networks, which have sometimes been called "invisible societies", are growing can be told from the fact that information group No. 7, barely a year old, had 1,100 members in April of this year and is expected to reach 2,000 by the end of 1966. The organizers of the scheme are now reaching the point at which they must apply for permanent financial support for a version of the experiment which has been running, and an appropriate request has apparently been made through the administration of the National Institutes of Health. At the same time, what is called *A Report to the Members* has been circulated by Dr. Errett C. Albritton, the director of the information exchange programme. This is valuable insight into the working of the information exchange and its problems.

Faster Publication

According to Dr. Albritton: "The overall objective [was] to accelerate the advance of medical science by subsidizing quick scientist-to-scientist communication on an experimental basis within a group of scientists (and later six more groups) in which there existed a high degree of identity of research interests". He argues that the informal exchange of information between scientists working close to each other in laboratories, or sharing the same coffee room, is a model for the kind of exchange of information that information exchange groups should promote. "Since taxpayer's dollars would support this experiment, the IEG had to be clearly differentiated from media of communication already serving science, and IEG's service had to be convincingly related to actual acceleration of the advance of science. The distinction between the service to science as proposed, and that supplied by journals, involved dimensional differences on two separate scales, one of speed of communication of research findings, the other of excellence of what was communicated. . . . Journals sacrifice speed to achieve excellence; IEG would sacrifice excellence—if it did not already exist in a communication—to achieve speed. If it did not already exist [sic], for many or even most of the communications in this subsidized professional correspondence might be of such high excellence that the journal would require no alterations whatever. But that would be an individual matter—the IEG would have no screening or review mechanism for assuring excellence."

Dr. Albritton compares the exchange of information within the exchange groups to the exchange of information at symposia and also cites the practice of the *Proceedings of the U.S. National Academy of Sciences*, in which papers submitted by members of the Academy are published without being refereed. He adds that the justification for spending taxpayers' money on such a scheme cannot simply be speed and that there must be "convincing reason to believe that the experimental operation proposed would actually accelerate scientific discovery and thus lie within the mission of the NIH". He quotes Dr. Philip Handler, one of the original sponsors of the information exchange groups, as saying that the chief object is to "accelerate the progress of scientific discovery" by updating "the frame of reference in which the scientist makes his day to day research decisions". There are said to have been two chairmen of information exchange groups who have supplied instances in which members were saved from embarking on projects because they learned, through the information exchange group to which they belonged, that the work had already been done elsewhere.

"Polls of membership by two IEG chairmen have supplied actual instances in which members were saved embarking on a project that another member had just completed, and instances of radical revision of plans, triggered by incoming information. Dr. Handler did not expect these spectacular instances to be frequent in occurrence; IEG's main impact would lie in the more informed decisions it made possible, throughout the research area, in *every* research laboratory.

"Sufficient documentation does not exist as yet for an appraisal of the impact IEG is having to accelerate the advance of scientific discovery. Statistical data on the average and range of the time-span between dispatch of scientific memos from the NIH print shop and the appearance of the same research findings in print in a journal are not as yet available. But the longer that time, the more near to 'actually current' is each recipient-scientist's frame of reference for his day-to-day research decisions."

On the cost of the system, the *Report to Members* has very little specific detail to provide. The cost for 1966 is said to be "by no means small" and equivalent to twenty average research grants. Dr. Albritton has calculated that if all the 18,000 recipients of National Institutes of Health grants were members of information exchange groups, the overall cost would be $5 million. This, of course, is probably a figure which takes account of the financial economies that would arise if there were even more members—in other words the present cost per member is likely to be greater than it would be when all National Institutes of Health grant holders were enrolled.

The *Report to Members* points out that the seven information exchange groups are formally autonomous. "The IEG Office does the observing, but otherwise serves only as a mail drop for scientists who wish to communicate their research findings speedily to their colleagues around the world. The experiment is costly and thus must be limited. These seven groups are regarded as a sufficient pilot run out of the 250 to 300 possible scientific groups the NIH might come to support."

Dr. Albritton's memorandum continues:

"*Priority.* Reference to priority in a recent memo from the writer needs elaboration. The IEG clearly has some of the attributes of a scientific society, formed, however, solely to speed communication. Basic in such a 'society'

is the observance of the ethics of priority. Without confidence in such observance, no scientist would care to accept membership. When the successive IEGs were organized, each, through its chairman and/or co-chairman, adopted as one of the conditions of membership the commitment to observe priority.

"One of the gratifying findings in the experiment has been the almost complete absence of any failure to observe priority, traced in its rare occurrence to a hasty reading of a memo received. The finding has been communicated to the membership for the benefit of any of the more recent members who may have less than complete security in quick communication of their own research findings.

"*Quoting Material in Memos.* The consensus among the IEG chairmen regarding bibliographic references to scientific memos may be repeated here for the benefit of the newer members. It is that inasmuch as a memo is not a 'publication' (it falls in the category of private professional correspondence), it may not be referred to in a bibliographic reference except as a 'personal communication' from the author of the memo. (It should, of course, be cited, if the writer of the published paper is a member of the IEG or has had access to an IEG memo through the courtesy of a member.) Prudence suggests that the writer of the paper [should] consult with the author of the memo to see if he still stands by the statement to be quoted. (Some IEG members make it a practice to dispatch at once to the author of a particularly interesting memo a request for a reprint of the article when it finally appears in a journal.)

"*Membership Policy.* Again for the sake of the newer members: Every research finding in an IEG's research area is potentially needed, quickly, by some member. If the finder is not a member, his findings are missing from the information stream. And just this much is missing from the stream's impact to accelerate research progress. Scientists *not* doing research in an IEG's research area belong in some other IEG, maybe yet to be formed; but scientists who *are* doing research in the IEG's limited area should be *in*, if they are capable of independent research.

"*The Recent Delay in Dispatch of Memos.* In the past two months the time between receipt of memos and their dispatch has been rapidly extended in the NIH Print Shop, until, in some instances, a memo has stayed in the shop as long as two months. This has been explained to us as temporary, due to a heavy load of research grants printing falling on the Print Shop at the same time as they were suffering from an unforeseen shortage of operating staff. The emergency has not ended at the time of this writing, but we are assured that they will try to move back to a week or ten days as their normal production time.

"*What is the Future for IEG?* The IEG remains an experimental programme. The chairmen and co-chairmen and other close observers believe IEG is here to stay. If it is, the programme will be taken out of the experimental category and will be able to extend its coverage to other research areas. However, still under consideration by higher administrators is the question whether the amount of acceleration IEG gives to scientific progress is worth the cost. An increase in speed seems a possibility; cutting costs is a possibility. Either should help toward an affirmative answer."

Dr. Albritton says that there has been an increase in the number of memoranda contributed by each member of the group as the years have gone by. He estimates that 80 per cent of the memoranda circulated at the beginning of the experiment eventually appeared in print in ordinary journals, and suggests that the present ratio is nearer 90 per cent.

It would, of course, be wrong to think that the volume of literature flowing into the National Institutes of Health can be processed without trouble. In an earlier note headed "Memos Must Be Camera-Ready!" Dr. Albritton advised members that "the IEG Office is receiving so many manuscripts (typescripts) each week that have to have additional work before they can be printed, that we are having to make a drastic change in procedure. Hereafter, memos that are camera-ready will be processed first and rushed on to the NIH print shop, but those requiring more work will be set aside in a waiting file—to be attended to when we can get to them. It is worth your investigating whether your secretary has the erroneous idea that a typescript that is 'journal-ready' is automatically also 'camera-ready'. What we send to the NIH print shop must be *ready for the camera*".

This note goes on to explain that pages must be numbered, glossy prints must be mounted, and that pages that have to be turned sideways must be legible when the top is turned to the left. By the end of the year (1966) Dr. Albritton expects that the delay in processing manuscripts before sending them to the "print shop" would be a month. He follows with practical advice "Addressed to Secretaries" which includes the helpful paragraph: "Now for a suggestion that will give more 'class' to the memo, if it does not seem too complicated to you. If all tables and all figures are segregated to the back of the memo, it gives more class to the printed job if FIGURES can head a right-hand page; and the same for TABLES, and the same for BIBLIOGRAPHY. Right-hand pages are odd, you remember. If one of these headings is about to be on an even-numbered page you can prevent it by inserting a blank page, giving it the even number, and proceeding on from there".

Why Not Get it to Us NOW?

Dr. Albritton writes:

Information Exchange Group No. 1, now entering its sixth year with over 700 members, has demonstrated conclusively that research findings can be disclosed through the IEG months before journal publication, *without jeopardizing priority*. In fact, it is now clear, the IEG has brought into existence *new and potent safeguards* to priority. The protective factors seen to exist within the IEG, that do not exist outside, may be pointed out:

1. Assume that a memo by scientist "*A*" contains a research finding that must be mentioned in a memo or published paper by scientist "*B*", else he fails to give *A* due priority credit. Every scientist is motivated to respect priority, but scientist *B* has added motivation: he has committed himself in one of the conditions of IEG membership. *B* honours his commitment in relation to *A* all the more in view of the fact that all his peers in the group are witness to *A*'s priority.

2. If *B*'s memo should actually fail to give *A* the priority credit due him, *A* has the opportunity to call it to *B*'s attention, privately, before the paper comes out in a journal. (If *B*'s paper is already in print, *A* still has recourse to the next procedure.)

3. If *A* does not get satisfaction from *B* in private correspondence, *A* can lay the matter before the IEG chairman. The chairman will, of course, satisfy himself that *A* has a valid complaint, but then can privately bring irresistible pressure on *B*. *A* also has the option of sending a memo through the Exchange.

There are now 2,500 members in the seven IEGs, and 1,200 memos have been transmitted, all *priority protected*. It is obvious, of course, that a paper sent through the IEG is better protected than one published without prior circulation through the IEG. Even more obvious: the earlier a paper is sent to the IEG Office, the surer the author can be that he actually will have priority. Surest of all will be the author who sends the paper through IEG as soon as the last page is pulled out of the typewriter. Waiting until it is accepted by a journal is an unnecessary precaution—the delay, even detrimental.

LIQUID STATE PHYSICS

By PROF. H. N. V. TEMPERLEY

Department of Applied Mathematics, University College, Swansea

LIQUID state physics has had a very curious history of leaps forward with periods of stagnation. The present advances were triggered by some extensive machine calculations published in 1957 (refs. 1 and 2). Because of the importance of the liquid state to almost every human activity, empirical knowledge abounds. Ever since the atomic hypothesis was taken seriously there have been attempts to understand the properties of liquids at a more fundamental level and it has probably always been realized that atoms and molecules show weak attractions at long distances and strong repulsions at short distances, and that the most characteristic properties of a liquid (a finite bulk modulus yet no resistance to shear) are somehow accounted for by such interactions. There are still many gaps in our knowledge; for example, we still do not know the most stable solid structure associated with any reasonable law of interaction. It is highly probable (but has not yet been formally proved) that the most space-saving way of packing spheres is in a cubic or hexagonal close-packed arrangement, but recent work by Bernal, Frank and others makes it plausible that various disordered arrangements become possible at densities only slightly less than close-packed. Intuitively it can be expected that a disordered structure can be distorted with little expenditure of energy if the average density is kept constant, so that the absence of permanent resistance to shearing forces can be understood.

So matters stood when van der Waals published his famous equation in 1873. This showed that the critical temperature of a gas, below which condensation becomes possible, could be understood as a balance between energy and entropy. Put in another way, above this temperature the effect of thermal agitation always overcomes the effect of the attractive forces between molecules and the substance fills the vessel uniformly; below this temperature, for sufficiently high densities, the attractive forces prevail and most of the assembly condenses. Very recently, rigorous work by Uhlenbeck and others has shown that a van der Waals's type of equation is the rigorous consequence of giving the attractive forces a range which is long compared with the molecular diameter. Forces between real molecules fall off fairly rapidly with distance, and it is now known that the corresponding equation of state would be more complicated analytically. Nevertheless, van der Waals's theory remains a very valuable first approximation to the description of condensation and the liquid state.

No real advances in our knowledge took place until the thirties and forties except the pioneer efforts of Lindemann (later Lord Cherwell), Braunbek, Born and others to understand how a solid crystal could become unstable at a sufficiently high temperature. These gave some very important insights, but the concept that was to be the analogue for a liquid of the lattice structure of a solid only emerged very gradually. This key concept is that of the distribution function, discovered experimentally in the twenties by X-ray studies of liquids. Imagine an observer standing on a particular molecule. Because of its finite size, neighbouring molecules can only approach to a certain distance. A typical molecule will be surrounded, on the average, by a "shell" of nearest neighbours, these in turn by a second "shell" and so on. The hypothetical observer would then see an average density of matter, oscillating with the distance from him with a period comparable with the molecular diameter, merging eventually into a constant density at very large distances from the typical molecule. This distribution function can be inferred from X-ray or neutron scattering experiments. In 1935 Kirkwood showed that it was in principle possible to calculate this function $g(r)$, the local density at a distance r from a typical molecule, theoretically, given the function $V(r)$, describing the interaction energy of two typical molecules at a distance r. At very low densities, the probability of finding two typical molecules at a distance r apart is proportional simply to the Boltzmann factor $\exp(-V(r)/kT)$; however, as the density increases, this has to be modified to allow for the fact that our typical pair of molecules is surrounded by others, the problem resembling the "self-consistent" calculations of quantum mechanics. By successive approximation we obtain a series expansion of $g(r)$ in ascending powers of the density. Various approximate summations of this expansion lead to integral equations for $g(r)$, which can be solved numerically if $V(r)$ is assumed known. The early studies of Kirkwood[3], and Born and Green[4], turned out to be rather unreliable at liquid densities, but we now have a considerably better understanding of the mathematics and physics of the problem of calculating $g(r)$, and thus of the equation of state, of a "simple" liquid like argon, for which the molecules can be safely considered to be spheres which interact with forces that are central and non-directional. (A molecule like water or alcohol has none of these desirable properties, and the theoretical study of such liquids is still at an early stage.) For simple liquids, methods now available enable the equation of state to be predicted to within a few per cent; the main uncertainty is now in our knowledge of $V(r)$ for real molecules.

It can be said that the direct study of the distribution function $g(r)$, which can be measured experimentally apart from its connexion with the equation of state, has practically superseded most other models of the liquid state, though these are still valuable physically. Among them we may mention the following:

(*a*) The "hole" model. A liquid was thought of as being like a crystal lattice from which some of the molecules are missing. If we suppose that the lattice becomes unstable when a certain percentage of places are empty we obtain a rough theory of melting.

(*b*) The "cell" model. A typical molecule is supposed to be confined to a small region of the liquid by the repulsive fields of its neighbours. Occasionally it can squeeze between its neighbours and migrate through the liquid, this process being associated with viscous flow.

(*c*) The "significant structure" or "cybotactic" model. A typical molecule is supposed to spend a proportion of its time in surroundings resembling a crystal and the remainder in a gas-like environment. This statement is to be understood statistically; the model does not actually assert that crystal fragments of various sizes are physically present in the liquid.

The experience with these tentative models has been very similar to that with the older theory of van der Waals, namely, that by suitable choices of constants some liquid properties can be accounted for numerically, while others are reproduced in order of magnitude. In the light of recent work it seems that such models stand or fall to the extent that they approximate to the surroundings of a molecule in a real liquid. These will certainly be something between those of a crystal and a gas, but the "significant structure" approximation is probably rather crude. The "cell" model takes account of just the first

"shell" of neighbours surrounding a typical molecule and smooths out the effect of the more distant shells, which are allowed for in theories involving the distribution function explicitly. The approximation behind the "hole" model is also rather rough.

Within the past five years there has been a considerable revival of interest in theories of the liquid state. This interest has been mainly confined to classical liquids. The theory of the two forms of liquid helium has followed the general lines laid down by Landau and Feynman with considerable success, but further progress probably awaits a better understanding of the fundamental theory of classical assemblies, with which this article is concerned.

In 1957 the theorist received a serious shock. Reliable machine calculations[1,2] then became available for the equation of state of the simplest assembly that has any claim to resemble a real liquid, the assembly of rigid spheres without attractive forces. At densities that can reasonably be considered to correspond to the liquid state (about 60–70 per cent of the close-packed density) it was found that none of the then available theories was satisfactory. The integral equation approaches due to Kirkwood[3], and to Born and Green[4], predicted pressures that, at such densities, were too low by factors of the order of three. The "cell" or "free volume" model fared almost equally badly, and it has since been found that it is a more appropriate description of the solid rather than of the liquid state. Finally, a comparison with an equation of state based on the first four virial coefficients confirmed what had long been suspected, that expansions in ascending powers of the density become poor at liquid densities, an impression that was confirmed by calculations of the fifth and sixth virial coefficients for this model.

Fortunately, theoreticians were not deterred by this challenge. Examination of the Kirkwood and Born–Green approaches showed that, by a piece of bad luck, the fundamental "superposition approximation" that they made becomes unreliable at unexpectedly low densities. It does correctly describe the initial departure of any gas from perfection and, in fact, also correctly reproduces the third virial coefficient, but will not bear the long extrapolations from densities at which departures of a vapour from perfection first become noticeable to the density of the liquid (which may be several hundred times greater). In 1958 Percus and Yevick[5] introduced a new form of integral equation, effectively based on the Debye–von Kármán picture of a solid (in which the normal modes are elastic waves, and the displacements of atoms from their equilibrium positions in the lattice are assumed to be small). They had to introduce a number of approximations of rather obscure significance in discussing how the spectrum of elementary excitations might vary with density, and how this spectrum of a liquid is related to that of a solid.

The proof of the pudding is in the eating; there can be no doubt that the Percus–Yevick equation fares better than most of its rivals in describing the consequences, not only of the "rigid sphere" interaction, but also of other interactions, such as the "Lennard–Jones 6–12" interaction, that are reasonably good representations of the attractions and repulsions of real molecules[6]. Direct comparison with experiment is inconclusive, even with a simple liquid such as argon—the interaction function is imperfectly known and interactions involving three or more atoms are perhaps significant. It has become usual, therefore, to compare the predictions of integral equations with Monte Carlo calculations of the equation of state for the same interaction, rather than directly with experiment, when trying to test their accuracy.

Why does the Percus–Yevick equation fare so very much better than the Kirkwood or Born–Green approach when it also involves approximations the effect of which is hard to assess? This question is under active investigation; so far only a few hints have emerged. Passing from solid to liquid densities involves a factor of only about 1·1–1·3 compared with factors of the order of hundreds when passing from vapour to liquid. A solid-like model thus has a better chance *a priori*. It has also been shown that some of the terms omitted by the Percus–Yevick equation tend to balance out[7]. These are only hints that make us ask for more!

The study of transport effects, initiated by Kirkwood in 1946, has also continued intensively, notably by Prigogine and his school in Brussels[8], and by S. A. Rice and his collaborators in Chicago[9]. Gradually we seem to be progressing from "order of magnitude" to reasonably reliable calculations of transport coefficients. As with equilibrium properties, some approximations are always necessary, and the penalties exacted for sloppy derivations or injudicious approximations can be even more severe than in equilibrium theory.

It is pertinent to ask what we can expect in the way of "technological fall-out". The conferences on the liquid state held in 1963, sponsored by the Institute of Physics and by General Motors, and the Washington Conference on Critical Phenomena held in 1965 all concentrated mainly on fundamentals. The same is likely to be true of a Faraday Society Discussion planned for April 1967. It is very satisfying that we seem to be approaching a situation in which we shall be able to relate equilibrium and transport properties of a liquid to the intermolecular interaction function in the sorts of ways that are already possible for a solid or gas, but can we expect spectacular developments in liquid state physics comparable with the transistor, the laser, the superconducting magnet, the special magnetic materials and the magnetic storage devices that solid state physics has given us?

It can justly be said that studies of equations of state are matters for experts only, but this is far from being the case with the closely related subject of phase transitions of liquids and solutions. A particularly striking feature of the 1965 Washington Conference on Critical Phenomena was its emphasis on the fundamental similarity of many different types of phase transition. In some cases the nature of the assembly and the precise details of the interaction seem to matter little, in others they can be crucial.

The technical importance of being able to predict in what circumstances a moving liquid will boil, emit gas, deposit a solid precipitate or freeze scarcely needs emphasis, yet the controlling factors are nearly always poorly understood. The emission of gas from a liquid can have very serious results, as in the formation of bubbles in the blood or in cavitation in pipes and near propellers, or in the formation of voids in castings. (In other cases, as in the design of pumps and impellers, it is possible to exploit the occurrence of cavitation. The lifting effect of gas bubbles in a liquid can help its circulation in certain types of process.) In other situations it may be very important to prevent the formation of bubbles. In certain types of bearing the lubricant is in a state of tension and it may be important to know in what circumstances one may expect to avoid cavitation. In botany various situations are known in which sap is under tension. The rising of sap appears to result, at least partly, from tension developed in the leaves by evaporation through the stomata[10]. The ejection of spores by the common fern arises[11] from the gradual drying out of certain cells, the liquid contents of which finally break, enabling the cell to act like a catapult when the tension is suddenly released.

It can also be important to know in what circumstances a liquid may be expected to freeze or to deposit a solid. As with gaseous solutions, a mere knowledge of equilibrium thermodynamics or statistical mechanics is not enough. It is well known that a solution of a gas or solid in a liquid can often be preserved indefinitely at considerable supersaturations if suitable precautions are taken, but why can some solutions supersaturate so much more than others? The equilibrium theory of solutions can be

said to be reasonably well understood and it has many similarities with theories of phase transitions, but non-equilibrium phenomena show many more idiosyncrasies than do equilibrium ones. Why, for example, can many liquids be obtained in a glassy state but others, such as water, can never be supercooled below a certain limiting temperature? When ice is formed from supercooled vapour, why can its crystal habit be changed quite a number of times within quite a small range of temperature? These are a few of the fascinating questions which are poorly understood, yet are likely to be of great technical significance.

Mention of the phase transitions of water reminds one of their meteorological importance. Condensation of water vapour plays a dominant part in cloud formation and is one of the main sources of energy of tornadoes and hurricanes. Many problems of cloud physics, such as the icing of aircraft, are closely related to the problems of the supercooling of water and of nucleation effects. So far, the progress of experiments in "rain making", and in modifying the course of hurricanes, by the artificial seeding of clouds has proved rather disappointing, but this is not a reason for saying that theoretical and experimental study of these matters is useless. The mechanism of electrification of thunderclouds is, according to some theories anyway, intimately associated with the freezing transition. The suggestion that an artificial thundercloud could be produced in the laboratory and then used as a cheap high voltage generator probably belongs to science fiction, but there is a strong case for careful study of effects associated with the freezing and evaporation of polar liquids (on which very little is known theoretically). One question of very considerable technical importance is a study of the factors that determine the rate of evaporation of a water surface. Can it be significantly retarded by any feasible surface treatment? If so, this would be of importance in irrigation and the management of reservoirs. Or can it be hastened? This would be of importance in the distillation of sea water and the design of boilers and related equipment.

Until very recently, it has been almost taken for granted that the interactions between ions in a liquid metal were of "many body" type. However, recent work by March[12] and his colleagues suggests that there is an effective interaction between ions not differing greatly from the "screened coulomb" interaction between ions in an electrolyte. Such work must lead, in due course, to better understanding of the crystallization and melting of metals. If the interaction can indeed be treated as effectively between pairs of ions only, the theoretical treatment becomes very much simpler than if it is of the many body type. Thus, we may expect this work to have considerable impact on metallurgy.

These are some of the likely direct benefits to various sciences of a study of the liquid state. Among indirect benefits mention can be made of the study of fluidized powders and slurries. A powder can be brought into a state bearing striking resemblances to a liquid if a gas is blown through it from below. The effect is that each particle is no longer completely imprisoned by its neighbours, but migrates over a certain "free volume". This relationship is very like that between neighbouring molecules in a liquid. Indeed, a fluidized powder can have a "free surface" and a "vapour phase" and can "find its own level" and have other properties very like those of a liquid. So far the study of fluidized powders has been mainly on empirical lines, but comparison with the "rigid sphere" model of a liquid is likely to be extremely fruitful, and should throw light on the transport of solid particles through pipes by liquids or by gases—a subject of considerable technological importance.

We indeed see a strange history of fundamental advances such as the discovery of the van der Waals equation, Kirkwood's pioneer work on the liquid distribution function and on transport coefficients and modern machine calculations on the equations of state of simple models having been separated by long gaps. At the 1963 conference in London a large number of experimental studies were reported, using techniques ranging from neutron scattering to spectroscopic study of melts, while theoretical work ranged from studies of "lattice" and other idealized models to the thermodynamics of mixtures. Although the subject is still mainly one for specialists it calls for relatively small investments of money and technical effort. Because it is hard to think of a science that is not in some way concerned with the properties of liquids and solutions, any advances in our knowledge seem certain to find applications somewhere. If one were asked to name a field in which a given expenditure of money and manpower were likely to produce a good return in the form of technological fall-out, this would be a likely choice.

This subject is also one in which cross-fertilization between industrial and university research is likely to benefit both. It may be quite feasible to carry out a continuous industrial process with a supersaturated solution which "ought", on equilibrium theory, to deposit a solid or to emit a gas, but a small alteration in the conditions may take one "over the hump" and thus bring the process to rest. At present, much effort is going into the study of the statistical mechanics of steady state and other non-equilibrium situations. This is just one example of cross-fertilization possibilities. Because virtually every science is concerned in some way with liquids and solutions other possibilities must abound.

So many of the properties of matter, especially when in the gaseous form, can be deduced from the hypothesis that their minute parts are in rapid motion, the velocity increasing with the temperature, that the precise nature of this motion becomes a subject of rational curiosity. Daniel Bernouilli, Herapath, Joule, Krönig, Clausius, etc., have shewn that the relations between pressure, temperature, and density in a perfect gas can be explained by supposing the particles to move with uniform velocity in straight lines, striking against the sides of the containing vessel and thus producing pressure. It is not necessary to suppose each particle to travel to any great distance in the same straight line; for the effect in producing pressure will be the same if the particles strike against each other; so that the straight line described may be very short. M. Clausius has determined the mean length of path in terms of the average distance of the particles, and the distance between the centres of two particles when collision takes place. We have at present no means of ascertaining either of these distances; but certain phenomena, such as the internal friction of gases, the conduction of heat through a gas, and the diffusion of one gas through another, seem to indicate the possibility of determining accurately the mean length of path which a particle describes between two successive collisions. In order to lay the foundation of such investigations on strict mechanical principles, I shall demonstrate the laws of motion of an indefinite number of small, hard, and perfectly elastic spheres acting on one another only during impact.

BOOK REVIEWS

PARANORMAL EVOLUTION

The Living Stream

A Restatement of Evolution Theory and its Relation to the Spirit of Man. By Alister Hardy. Pp. 292. (London: William Collins, Sons and Co., Ltd., 1965.) 30*s*. net.

THE Gifford Lectures, delivered annually at the University of Aberdeen, were intended by their founder, Lord Gifford, for "promoting, advancing, teaching and diffusing the study of Natural Theology, in the widest sense of the term". This has provided considerable scope for lecturers in past years; the list of past lecturers is an impressive one, including, among others, philosophers, physicists, astronomers, theologians and a distinguished physiologist. The series of lectures during the session 1963–64 were given by a distinguished zoologist, Sir Alister Hardy, and the first of the series has now been published under the title *The Living Stream*.

Hardy approaches the task assigned to him primarily as a student of the evolutionary adaptation of animals to their environment, and, in agreeing with the definition of natural theology as a theism which is derived empirically from the study of nature, man and human history, he is concerned to emphasize that current ideas of evolution are not fully explanatory of this process. "I venture to suggest", he writes, "that there is something more about the process of evolution than is generally conceded by most biologists today; and this 'something more' does, I believe, link natural theology to the biological scheme". It is not easy in a short review to summarize, without doing injustice to his various lines of reasoning, all the arguments on which the author relies for substantiating his main thesis, particularly as this book may be assumed to be a general biological survey intended to preface the second series of lectures that now await publication. Hardy makes it clear in his introduction that, while rational theology has usually maintained that God's existence could be proved by reason alone, "to this I do not subscribe". He also makes a distinction between natural history as "the qualitative description of nature" and science "the quantitative and experimental analysis of its interactions". Whether such a distinction is accepted as valid or not, some may find it difficult to accord these preliminary statements with the exhortation in the last sentence of the book that we need to "show the way to a re-establishment of the idea of God as both a philosophical and scientific reality". But the inconsistency of thought implied in these references is perhaps more apparent than real when considered in relation to the detailed discussions generally. The author gives a remarkably lucid and concise account of the development of modern evolutionary ideas and the nature of the gene, and he agrees that selection acting on small random changes in the inherited nuclear material is the main physical mechanism of evolutionary change. He lays particular emphasis on the consciously directed behaviour of animals in seeking out new environments, or in attempting to adapt themselves to changing environments, as one of the most important factors for evolutionary progress by providing the opportunity for the selection of appropriate mutations as they arise. Further, he envisages a "group mind" or a "species mind" representing a psychic side of animal life, and determining certain configurations of form and behaviour unfolding automatically according to the DNA code of the particular species concerned. He suggests, however, that the psychic side of an animal may be independent of the DNA code, though it may also interact with the physical system in the evolutionary process through organic selection. Finally, he invokes the phenomenon of telepathy (in his view, as well as in the view of other students of psychical phenomena, well established by experimental tests such as card guessing) for an explanation of the rapid and widespread development of new behaviour patterns among different geographical groups of the same species.

No doubt there are those who will feel disinclined to follow Hardy so far in such a speculation, but it is well to note that he himself remarks that "these fancies, without more facts and experiment, lead to folly". Indeed, he goes on to say "I do not expect that my speculation is right, but by being shown to be wrong or impossible it may give rise to better thoughts which may help towards a solution of some of our conundrums". It will be at once admitted that to disprove a hypothesis of communication by telepathic means between individuals of a species would certainly be very difficult indeed. But the question will inevitably be asked whether it is in fact necessary, or useful, with our present knowledge of the potentialities of known evolutionary mechanisms, to postulate a conception such as telepathy as an additional factor determining biological adaptations. Opinions will no doubt vary widely on this matter, but all readers of Hardy's book will share the opinion that it is eminently readable as well as being pleasingly provocative.

W. E. LE GROS CLARK

MUSCLE CONTRACTION

Molecular Biology of Muscular Contraction

Edited by S. Ebashi, F. Oosawa, T. Sekine and Y. Tonomura. (BBA Library, Vol. 9.) Pp. xii + 206. (Amsterdam, London and New York: Elsevier Publishing Company, 1965.) 110*s*.

RECENT research has simplified our ideas on the biochemistry of skeletal muscle and there is now widespread acceptance of the grosser aspects of contraction: contraction occurs as the result of rigid filaments sliding past one another; energy is provided by the hydrolysis of ATP and calcium released from the sarcoplasmic reticulum provides the trigger for contraction. This has led to a division of interest among research workers. On the one hand how does the action potential cause the release of calcium, and on the other hand how is this calcium able to elicit contraction of the myofibril? In either case the interest lies in the explanation of these events at the molecular level.

Molecular Biology of Muscular Contraction is a tribute to Prof. Kumagai, who has done much to foster the vigorous groups in Japan working on muscular contraction. It was his discovery of the granular nature of the relaxing factor that paved the way to its identification as fragmented sarcoplasmic reticulum. Nineteen contributions from the United States and Japan cover many aspects of the field. However, considering the title of this book, it is unfortunate that no mention is made of the molecular architecture of the filaments. The absence of a paper on tropomyosin is also surprising as Japanese workers have been largely responsible for elucidating the role of this protein in the myofibril.

The papers are divided into six sections on ion binding, myosin, actin, actomyosin, comparative aspects of muscle

and contraction–excitation coupling. Singling out a few papers for mention, Tonomura and co-workers summarize and interpret their data on the kinetics of the interaction of ATP analogues with myosin systems. Kielley reviews his evidence for the existence of three polypeptide chains in myosin and for the arrangement of the meromyosin moieties within the molecule.

The role of the bound nucleotide of actin remains a challenging issue, and Oosawa and his colleagues conclude that, while not indispensable, it does exert a large effect on actin polymerization. They also contribute new evidence that conformational changes in the actin polymer occur during contraction.

A salutary warning to biochemists, who perforce are often obliged to use mixtures of red and white muscle, is given by Gergely and his co-workers. They find very large differences in the properties of fragmented sarcoplasmic reticulum, of the myofibrils and even of the purified myosin obtained from red and white fibres. They make the interesting suggestion that red muscle myosin may be related to cardiac myosin. Finally, Ebashi discusses how the action potential arriving at the central tubule of a triad could elicit the release of calcium at the lateral vesicles.

My main criticism of this book is that the contributions are specialist in nature and are not general reviews. Thus the book cannot be recommended to students and others unfamiliar with the field, whereas there certainly is a need for a modern text-book on the subject.

G. W. OFFER

VETERINARY CODEX

British Veterinary Codex 1965

Pp. xxxv+843. (London: The Pharmaceutical Press, 1965.) 105*s*.

THE long-awaited new edition of this book follows closely the layout and content of its predecessor. As an authoritative reference book for those concerned with the manufacture, supply and use of drugs in veterinary practice, it will no doubt continue to be of great value. It is unfortunate, however, that an interval of twelve years should elapse between editions even when an interim supplement is published.

The *Codex* consists of three main parts; monographs on drugs and chemicals, on antisera and vaccines, and a formulary. This is followed by seventeen appendixes and a therapeutic index.

Part I has been extensively revised by the addition of 56 new monographs, while 106 have now been deleted. Several drugs in current use are not included. I was struck in particular by the absence of griseofulvin, while acepromazine, bendrofluazide, framycetin, heparin, phencyclidine, tripelennamine and tylosine are also missing. Conversely, is it still necessary to include camphor, chenopodium and rhubarb? The monographs are generally useful and informative although the description of the administration of halothane (p. 180) did not impress. The potential toxic hazards of stilboestrol implantation in lambs are not mentioned, although similar effects in cattle and poultry are noted.

Part II (biological products) has been revised and contains several additions. Four new appendixes have been added, including a useful section on pharmaceutical adjuvants. The appendixes on feed supplements and gas–liquid chromatography are, however, too short to be of any great value. Brief descriptions of complex subjects are rarely satisfactory and adequate enlargement could scarcely be justified in a veterinary codex. The therapeutic index is also of limited value, although it could be useful for reference or possibly in an emergency.

This is an essential publication which would benefit from more frequent revision, so that changes in the field of veterinary therapeutics can be more rapidly assimilated.

J. SANFORD

FROM WOAD TO WEED

Weeds of the World

Biology and Control. By Lawrence J. King. (Plant Science Monographs.) Pp. xxxii+526+23 plates. (London: Leonard Hill; New York: Interscience Publishers, Inc., 1966.) 105*s* net.

THIS book is another volume in the Plant Science Monograph series, which is designed primarily to bring together the scattered literature of important specialities in the plant sciences, with the ultimate and indirect object of helping to feed and clothe the increasing world population and to improve productivity and hence living standards. There can be no doubt of the suitability of weeds as a subject in this series, nor of the need of a review of research in this subject. The present book, announced at least five years before publication, aroused high expectations, so that it is a pity to have to register a measure of disappointment.

The first eleven chapters are devoted to weed biology in the widest possible sense of both words. One of the objects of these monographs is to cover all aspects of the subject concerned, and Dr. King has certainly attempted to do this, even to the extent of listing some of the more extraordinary uses to which man has put weeds, from using a *Lithospermum* for contraception to an *Angelica* root as a talisman for gamblers. The chapters are a series of reviews, each with its relevant bibliography, and the author has made much use of original publications, especially for their graphical and pictorial material. In the first chapter there is a lengthy consideration of the words used for weeds in several languages, from the possible origin of "weed" from "woad" (*Isatis tinctoria*) in English, to the interpretation of Chinese and Japanese ideographs. Various definitions of weeds follow and these too are considered in detail.

Having started in such detail and diversity, it is perhaps not surprising to find a certain imbalance in the volume. Matters that might have furthered the aims of this series, such as the significance and increasing importance of rhizomatous weeds in certain systems and areas of agriculture, are mentioned only in scattered references, whereas the importance of weed seeds is well considered, presumably in view of the author's association with the Boyce Thompson Institute.

The four chapters on weed control could well have been omitted: they add nothing to existing works and are noticeably dated. For example, in a book published in 1966, where (apart from one list in an appendix) are the bipyridyls? In addition, the naming of herbicides is inconsistent and the primary authors are not always quoted. This is the case with the grouping of triazines on structural affinity.

Despite these criticisms this is a valuable book, which will undoubtedly be read to great profit by all those interested in weeds, for it refers frequently to earlier biological or more purely botanical publications that are not always appreciated or even discovered by those involved in more practical aspects. R. J. CHANCELLOR

PLANT LATIN

Botanical Latin

History, Grammar, Syntax, Terminology and Vocabulary. By William T. Stearn. Pp. xiv+566. (Edinburgh: Thomas Nelson and Sons, Ltd., 1966.) 105*s*.

SYSTEMATIC botany is probably the only discipline which uses Latin as a regular, indeed compulsory, means of

communication. Under the International Code of Botanical Nomenclature no new taxon can be validly published without at least a diagnosis in Latin, so some knowledge of botanical Latin is essential to every working taxonomist.

It is therefore remarkable that no guide to the subject in English, other than more or less complete glossaries, has been published for more than a century. Dr. Stearn's book supplies what is, for once, really a long-felt want, and does it with his usual accuracy, wide knowledge and eye to practical needs.

After a brief introduction to the method of using the book the reader is entertained with a history of the development of botanical Latin terminology, which is valuable not only for an understanding of modern Latin but also for the interpretation of earlier works.

In the second section of the book some 70 pages are devoted to grammar, and here hard work for the reader begins. The young systematist with no previous knowledge of Latin will have to make a determined effort, if he is really going to master this without assistance. It may in fact prove better to pass on to the third section, syntax and other matters, and try to model a diagnosis or description on one of the many good examples given in this part and then to get it corrected, and so learn by trial and error. The examples are drawn from all groups of plants, except bacteria and fossils; therefore a wide range of terminology is available. In addition there is an extensive vocabulary at the end so that by selecting appropriate words and substituting them in the chosen example the beginner can get quite a long way.

If an adverb is being sought, the list on pages 105–107 should be consulted, as well as the vocabulary, as there are differences between them both in content and, to a lesser extent, in the English equivalent given. A few examples, taken at random, will illustrate this: the vocabulary lists *abundanter* and *copiose*, which are absent from the list, and gives *disgustingly*, *badly* as the meaning of *putide*; the list has *infauste*, missing from the vocabulary, and gives *badly*, *absurdly* as the meaning of *putide*.

Other valuable special lists are those dealing with geographical names, colour terms etc., while lichenologists and phycologists will find the list of chemical names particularly useful.

Dr. Stearn claims that botanical Latin should be regarded as a language distinct from classical Latin and most botanists would support this claim at least as far as it justifies the simplification of grammar, the use of a much bigger range of colour terms and other new words or words used in special senses, and the retention of certain non-classical spellings such as *bacca* and *annulus*. To argue the case further is a matter for the language expert. A professor of classics once remarked that botanical Latin was the kind of Latin the Romans would have used if they sent telegrams, that is clear, simple and concise.

Altogether this is a most useful and interesting book from which beginners and experts alike can profit. It has already been used in an unexpected way by a botanist with a knowledge of Latin but little acquaintance with English to produce English descriptions of plants.

T. G. TUTIN

"PHYSICS OF THE OCEANS"

Elements of Physical Oceanography

By Hugh J. McLellan. Pp. ix+150. (London and New York: Pergamon Press, Ltd., 1965.) 63*s*. net.

THE increasing interest in oceanography in recent years has given rise to a number of popular books on the subject, while a succession of review volumes at the research level has appeared, summarizing advances in special fields. At the same time, the student coming to the subject with no systematic knowledge of it and requiring a sound treatment of its principles has found a very meagre selection of texts. This book by Prof. McLellan is a valuable contribution to filling this gap, so far as physical oceanography is concerned. It is based on a course of lectures given at Texas A and M University and it bears the mark of having been written by a teacher who knows from experience what questions students will ask and which points they will find difficult. It is intended to provide a broad look at the subject, for biologists, chemists and geologists, as well as for physical oceanographers. The treatment is necessarily selective, but is sufficiently representative of the whole field, and each topic is treated rigorously within the limits which the author sets himself.

The three parts into which the book is divided deal respectively with descriptive oceanography, oceanic movements and selected topics. Starting with a view of the oceans in perspective, Part I goes on to describe the chemical nature of the ocean, the measurement and distribution of temperature and salinity and the fields of density and pressure. This leads to a discussion of water masses and a description of the general oceanic circulation. The basic dynamical concepts are well explained in Part II, including a good discussion of geopotential surfaces and stability. Geostrophic currents, wind drift, turbulence, inertial motion and waves are among the subjects treated, and this part ends with a brief description of tides. Two of the chapters in Part III deal with light in the sea and the heat budget of the ocean, essential topics in a study of physical oceanography, and these are followed by a brief chapter on thermohaline circulation. The other two selected topics are sound propagation and estuaries.

There is only one point about which I feel inclined to quibble and that is the indiscriminate use of the terms "force" and "acceleration" in dealing with the effects of the earth's rotation. It is disconcerting to read of "centrifugal acceleration" away from the axis of rotation and "Corilis acceleration" acting to the right of a moving element in the northern hemisphere. This confusion in nomenclature is not a feature peculiar to this particular book, however.

The book is well illustrated throughout by appropriate diagrams. Those taken from other sources are wisely selected and clearly reproduced and the original ones are also simple and clear. There are useful lists of references and sources of additional information at the end of each chapter.

K. F. BOWDEN

ELECTROMAGNETISM IN GEOPHYSICS

Electromagnetism and the Earth's Interior

By Tsuneji Rikitake. (Developments in Solid Earth Geophysics, Vol. 2. Pp. xi+308. (Amsterdam, London and New York: Elsevier Publishing Company, 1966.) 130*s*.

MANY advances have been made in the study of the Earth's magnetic field since 1940, when Chapman and Bartels first published their treatise *Geomagnetism*. In that comprehensive work the absence of an adequate theory of the source of the field was notable, and in this direction particularly significant developments have taken place. Prof. Rikitake's book is an up-to-date account of theoretical geomagnetism and it reflects how much more satisfactory our understanding of the fundamental processes has become in recent years.

The book falls into two main parts. The first deals with the main geomagnetic field, giving a wide-ranging review of the theories of its production and its long period variations. Here the author (rather cautiously) advocates the self-exciting dynamo mechanism and he shows how this accounts successfully for most of the observations.

The second part of the book is concerned with electromagnetic induction in the mantle and the oceans, produced by magnetic fluctuations. Highly detailed mathematical theories are developed to cover all the various cases, including the thin-sheet approximation to deal with ocean screening and the spherically symmetric model for the Earth as a whole.

The author's approach has been to survey the original papers, many of them his own, choosing certain of them for detailed exposition. Here I think Prof. Rikitake is open to criticism. The book would have benefited greatly from a more unified approach instead of the mixture of styles and notations resulting from adhering closely to the original sources. An important gain from this would have been a new emphasis on the fundamental principles. For example, the choice of particular papers given detailed analysis in the first section does not seem to me to be very sensible. Many pages are devoted to the rather unsatisfactory Inglis model for field production, while the basic papers of Bullard and Gellman and of Elsasser are given much less space. I also feel that if he had considered the overall logic of the book more carefully the author might then have included more discussions of the physics involved, rather than being carried away by the mathematics as sometimes happens in the present volume.

As the book stands it represents a fairly complete summary of the important work in this field. The list of references is excellent so that the reader may easily follow up any line which is not fully dealt with in the text. The diagrams are clear and the mathematics well produced. There are a few printing mistakes and in places the English is idiosyncratic, but this does not seriously detract from the general readability of the work. Prof. Rikitake has performed a useful service in gathering all this material together in one volume, but I feel the work would have been more valuable if he had developed the subject logically from the physical background in his own way.

R. L. PARKER

FLUID FLOW

Flow Measurement by Square-edged Orifice Plate Using Corner Tappings

By W. J. Clark. Pp. xiii + 226. (London and New York: Pergamon Press, Ltd., 1965.) 200*s*. net.

THE square-edged orifice plate meter is probably the simplest device available for metering the flow of fluid in a duct, and, for that reason, it is the most commonly used instrument. Large quantities of often valuable fluids can flow through such a meter and it is necessary to ensure that the orifice plate is correctly installed if the flow readings are to be accurate. This monograph is the result of Dr. Clark's experience with vast numbers of such instruments in a large chemical works, and methods of designing such metering installations are described using charts and a special slide-rule to calculate the orifice diameter and flow characteristic. A number of specimen calculations and installations are included and the importance of regular maintenance is emphasized in what is essentially a practical approach to the subject.

It is inevitable that many of the data presented in the monograph are basically the same as those contained in the British Standard on flow measurement (*B.S.* 1042: 1964). The use in the text of non-standard Reynolds number correction factors could give rise to a little confusion, although this does perhaps illustrate the point that metering perfection cannot be expected even under ideal laboratory conditions.

The monograph contains a fuller examination than is usual of the influence of flow pulsations on metering errors, although it is a little disappointing that the author has not included references to the more recent work in this field. While Dr. Clark emphasizes that, in the majority of cases, errors due to this effect are negligible, the difficulty lies in detecting the presence of such errors. The cases brought to my notice have usually arisen where a user has observed a plant thermal efficiency greater than 100 per cent, or where the indicated flow is in the opposite direction to the known mean flow. Less extreme cases often go unnoticed, as a steady meter reading is so easily confused with an accurate one. Dr. Clark devotes his attention mainly to the pulsation errors associated with the flow through the orifice or primary element, but the errors often spring from the manometer not indicating the true time mean of the pressure differential. Greater attention could have been given to the possible sources of these manometer errors and to the conditions necessary for their elimination. For example, the advice that damping should be confined to the manometer liquid rather than to the leads could be challenged, as linear damping devices in the leads near the orifice connexions can prove very successful in eliminating manometer errors. Symmetry in the manometer lines is no guarantee of accuracy since equal volumes in both lines can produce errors of the order of 100 per cent.

T. J. WILLIAMS

ORGANOMETALLIC COMPOUNDS

Advances in Organometallic Chemistry

Vol. 2. Edited by F. G. A. Stone and Robert West. Pp. ix + 440. (New York: Academic Press, Inc.; London: Academic Press, Inc. (London), Ltd., 1964.) 107*s*. 6*d*.

THE intensified study of organometallic compounds, as well as notable extensions in the field they embrace, makes the appearance of volumes such as this a dire necessity for chemists. Surely it is here, if anywhere, that all the main branches of chemistry meet and overlap. But perhaps for that very reason there is a subconscious tendency to regard organometallic chemistry as "nobody's baby", and nowhere has this been more apparent hitherto than among the compilers of reviews.

The present volume, under its able editorship, maintains the aims and standards of the first. The titles of the chapters are well chosen and avoid overlap with the first volume, but that is not to suggest that they fill in more than a very few of the gaps it left, and chemists will be hoping that this matter will in time be rectified by the due appearance of further volumes in fairly rapid succession. The one now presented is comprised of seven more or less extensive reviews written by specialists in the respective subjects, each review being subdivided into sections.

The alkali metals, nickel and boron, are particularly well represented. Indeed, well over half the book is devoted to some aspect of their chemistry, so that workers interested in these elements will find this volume especially important. It should be emphasized that the review by R. Köster is not the same as that entitled "Organoboron heterocycles" which he published almost simultaneously in *Prog. Boron Chem.*, **1**, Chapter 7, but is quite different in presentation and to a large extent also in the material incorporated. The subject is in any case too vast to be conveniently covered by a single review, so that Koster's two reviews can be regarded as complementary.

The various chapters are not all equally exhaustive in the treatment of their subjects, but in this respect those by H. A. Skinner, R. B. King and J. Birmingham on the strengths of metal-carbon bonds, the reactions of alkali metal derivatives of metal carbonyls and related compounds, and on the synthesis of *cyclo*pentadienyl metal compounds, respectively, may be singled out as coming to full comprehensiveness. It was almost inevitable that *cyclo*pentadienyl and allyl complexes of nickel each come up for treatment in two different chapters, but otherwise there is no overlap. The chapters are all well written, and one is scarcely ever aware that English is not the mother tongue of several of the authors. Indeed,

the only serious criticism one can make against this volume is that, in the absence of a formula index, the six-page subject index is much too brief and no reliable guide as to what may be found in the book. There is a twenty-page author index. L. H. LONG

GASEOUS OXIDATION PROCESSES

Oxidation and Combustion Reviews

Vol. 1. Edited by C. F. H. Tipper. Pp. 344. (Amsterdam, London and New York: Elsevier Publishing Company, 1965.) 80*s*.

THE series *Oxidation and Combustion Reviews* is intended to deal with both pure and applied aspects of oxidation and combustion—a wide field in which chemistry, physics and engineering overlap. The first volume concentrates on chemical aspects of oxidation by molecular oxygen. Nevertheless, the field covered is wide; oxidation both in the gas phase and at the surfaces of solids is dealt with in six chapters by different authors.

The first chapter, "Application of the Theory of Branched Chain Reactions in Low Temperature Combustion", by R. Ben-Aim and M. Lucquin, gives a brief but useful summary of the theories of self ignition and describes some of the methods of studying it. It then discusses the application of these to real oxidation systems, dealing particularly with the cool flames of hydrocarbons and of their oxygenated derivatives. The morphology of cool flames and associated phenomena is well reviewed, but important recent developments in our knowledge of the chemical mechanism of oxidation under these conditions are given too brief a treatment.

"Oxidation Reactions Induced by Ionising Radiation", by G. Hughes, provides a useful catalogue of the reactions that occur when high energy radiation interacts with substrates containing oxygen. The author purposely excludes the irradiation of aqueous solutions, concentrating on the less-well-documented reactions of pure inorganic and organic substrates.

"Gas Phase Photo-oxidation", by G. R. McMillan and J. G. Calvert, compares photo-oxidation with thermal oxidation as a method of providing reliable information on elementary combustion reactions. Many examples are given (and critically discussed) of the derivation of rate constants and other mechanistic information from the results of photo-oxidation experiments. The elementary processes discussed include reactions of alkyl, acyl, alkylperoxy, peracyl and alkoxy radicals. The chapter is well written and logically presented.

The fourth chapter, "Oxidation Reactions involving Nitrogen Dioxide", by J. H. Thomas, is a good, up-to-date, descriptive review. It describes in detail recent kinetic work on the use of nitrogen dioxide as an oxidant, as a sensitizer and as an inhibitor in gas phase oxidation reactions. Slow combustion, flames and explosive reactions are all reviewed and particular attention is paid to the controversial nature of the initiation step in reactions involving nitrogen dioxide. Nitration reactions are, however, excluded.

In the fifth chapter, "Oxidative Degradation of High Polymers", W. L. Hawkins describes the deleterious effects on polymers of thermal and light-induced oxidative degradation and discusses methods of retarding these reactions. The "hydroperoxide chain theory", which describes the autoxidation of volatile hydrocarbons, is applied to the oxidation of hydrocarbon polymers, and ways are suggested in which this mechanism must be modified to apply to non-hydrocarbon polymers. No mathematical treatment of polymer degradation is included, but the qualitative treatment of the possible reactions involved is good.

The book ends with "The Heterogeneous Selective Oxidation of Hydrocarbons", by R. J. Sampson and D. Shooter, which describes the effects of the physical and chemical properties of solid catalysts in determining the selectivity of oxidation processes at their surfaces. These processes are exemplified by the oxidations of ethylene to ethylene oxide, propylene to acrolein, C_4 hydrocarbons to maleic anhydride and to butadiene, and aromatic hydrocarbons to anhydrides. As well as considering the basic mechanism of these processes, the authors present results of practical interest, listing 122 references to the patent literature. The chapter would benefit, however, by the inclusion of a summary of factors affecting selectivity (so far as they are known) at the expense of detailed description of results.

The volume as a whole is a mine of useful information on gaseous and gas–solid oxidation processes; it is recommended for workers in these fields. A. FISH

Anthology of Orthopaedics

By Mercer Rang. Pp. xi + 243. (Edinburgh and London: E. and S. Livingstone, Ltd., 1966.) 42*s*. net.

SOME medical authorities dislike eponyms: others, particularly medical historians, commend them as giving honour to the discoverer of a disease or injury or its first exponent. In this well-written book Mr. Rang, senior lecturer in surgery at the University of the West Indies, studies his specialty historically, and gives us not only a brief biography of each surgeon or eponymous author, but also an extract from the book or journal in which the condition was first described. Portrait sketches are included as well as anatomical drawings, X-ray photographs and descriptions of apparatus and splints.

Mr. Rang states in his preface that the book is not comprehensive and a number of omissions of orthopaedic eponyms will be noted by experts; but, on the whole, the more important ones are given, in addition to others less well known.

Orthopaedics is a comparatively modern specialty. Formerly, it was practised by the general surgeon who took a special interest in the subject. Physicians and neurologists also have contributed to orthopaedic eponyms. Hippocrates wrote a book on fractures and another on articulations. Paul of Aegina (625–690) described ganglion in a tendon and its treatment. W. J. Little (1810–94) introduced tenotomy into Britain after studying Stromeyer's results in Hanover. Intending to be a surgeon, he founded the Royal Orthopaedic Hospital which is now the Royal National Orthopaedic Hospital in London. He turned from surgery to medicine, became physician to the London Hospital, and wrote on tenotomy, club foot and scoliosis. He described the spastic state caused by birth injury to the brain, which is known as Little's disease. A pioneer in specialized orthopaedics was the general practitioner, Hugh Owen Thomas (1834–91), who invented the Thomas splint and advocated prolonged rest for tuberculous joints. His nephew, Sir Robert Jones (1857–1933), specialized entirely in orthopaedic surgery from 1905 and, with Dame Agnes Hunt, founded the Robert Jones and Agnes Hunt Orthopaedic Hospital at Oswestry. Another famous pioneer was Sir Henry Gauvain (1878–1945), who obtained successful results through the open-air treatment of bone and joint tuberculosis. He described spasm of the muscles around the affected hip joint as a diagnostic sign of tuberculosis. Jones and Gauvain by their work made orthopaedics a specialty. ARTHUR MACNALTY

The Determination of Toxic Substances in Air

A Manual of I.C.I. Practice. Revised edition. Edited by N. W. Hanson, D. A. Reilly and H. E. Stagg. Pp. xii + 200. (Cambridge: W. Heffer and Sons, Ltd., 1965.) 50*s*.

THIS book, which was first issued in 1956, has been revised by a sub-committee working under the general

direction of the Analytical Methods Committee of Imperial Chemical Industries Limited. The revised edition, like its predecessor, is a manual of Imperial Chemical Industries practice, consisting mainly of the description of methods of analysis for the determination of low concentrations of a range of toxic substances found in factory atmospheres. New or improved analytical methods up to the end of 1963 have been examined for some sixty substances or groups of substances, and details are given, for each selected method, of the apparatus and reagents required, the sampling and test procedures and the calculation of results.

For many substances several test procedures, which fall into three categories, are described: rapid field tests based almost entirely on the series of booklets *Methods for the Detection of Toxic Substances in Air* published by H.M. Factory Inspectorate, Ministry of Labour; more precise methods including gas chromatographic techniques which require the facilities of a laboratory; and indicator tube tests for selected substances with the commendable advice to all users to follow Imperial Chemical Industries practice and calibrate each batch of tubes before use by means of atmospheres of known composition.

Brief descriptions are also given of the apparatus required for sampling industrial atmospheres (18 pp.), chemical methods of measuring toxic substances in air (8 pp.) and, in a chapter new to this edition, static and dynamic methods of preparing atmospheres of known composition (7 pp.).

Although there is a growing awareness in industry of the need to protect workers from the hazards of repeated exposure to low concentrations of air-borne contaminants, few books describing suitable methods of air analysis are available. This compilation of methods based on the wide experience of a large industrial organization is a welcome contribution to the subject. The book is well arranged, clearly and concisely written and contains useful diagrams, an ample index and adequate references. Without doubt it will be consulted frequently by those interested in the field of industrial hygiene. A. A. CHRISTIE

Calculus of Variations and Partial Differential Equations of the First Order

By C. Carathéodory. Part 1: Partial Differential Equations of the First Order. (Holden-Day Series in Mathematical Physics.) Pp. xvi+171. (San Francisco, London and Amsterdam: Holden-Day, Inc., 1965.) $8.50.

CARATHÉODORY'S *Variationsrechnung* first appeared in 1935 and was reviewed in *Nature* in the November 23 issue of that year. Part I of the book, entitled "Partial Differential Equations of the First Order", is described in that review as "an account remarkable . . . for lucidity and completeness"; and the review of the whole work concludes with the sentence "In sum, this book is indispensable".

In the 30 years since the publication of Carathéodory's book many advances have been made in the mathematical theory of partial differential equations, but most of these occurred in branches of the theory outside the area covered by Carathéodory, and the latter's book remains a classic. In view of continuing interest, Hölder edited a (German) reprint of Part I. The present translation is based on this reprint, which appeared in 1956 and in which a few minor errors, both typographical and mathematical, were corrected, some short comments were added in the text or in footnotes, and a brief supplement was provided.

Carathéodory's presentation of partial differential equations of the first order combines geometrical insight with analytical rigour, and the availability in English of this presentation will be welcome to many. The English translation is by J. J. Brandstatter of the Stanford Research Institute and is always accurate, and mostly readable and idiomatic. A. ERDÉLYI

MEETINGS

INTERNATIONAL NUTRITION

THE members of an international congress of biochemists concern themselves with biochemistry, and pure and applied chemists in the main discuss chemical science. Even physicists when they meet restrict themselves to matters of physics, leaving discussion of nuclear power to engineers, military strategists and politicians. At the seventh International Congress of Nutrition held in Hamburg during August 3–10, however, three kinds of discussions took place. The first of these comprised strictly scientific reports of experimental studies and clinical investigations, and the second were surveys of food intake in relation to nutritional requirement and population density; both clearly relevant to the professional competence of the participants of the congress. But who is professionally qualified to say how one nation, once poor, develops and becomes rich, why another falls into anarchy, poverty and malnutrition, while a third, desperately embracing technological innovation, loans, gifts and advice nevertheless fails to improve the lot of its population and while categorized as a "Developing Nation" finds itself unable to develop?

Perhaps nutritionists are unwise to argue as hotly as they do that nutrition is a science. Biochemistry budded off as a part of physiology, and nutrition—as a scientific speciality—was in its turn an offshoot of biochemistry. But nutritionists, having established themselves by such studies as the chemical analysis of foodstuffs, elucidation of the crystalline structure of thiamine (vitamin B_1) and of its biochemical mechanisms, have extended their territory to include "Food Habits in Pre-industrial Societies in Mezoamerica", "Rituals and Taboos" and "Poverty Dissected: An Anatomy Lesson in Rural Paraguay"—to cite just three of the papers read at Hamburg. It is true that the traditional customs in Central America and taboos and rituals in primitive and sophisticated countries alike exert an important influence on the foods the people eat and on their consequent state of nutrition. But a scientist whose authority depends on his training in biochemistry and physiology is an amateur when he attempts to draw deductions about matters on which the judgment of an ethnologist is needed. Understanding of the habits and customs of a nation or tribe will be as baffling to a dietitian educated in Boston who is mistakenly attempting to introduce the bottle feeding of infants into Tanzania as will the oddity to a visitor from Central Africa of the fact that the British are happy to receive pooled blood plasma by injection although during the Second World War they refused with disgust to allow the Ministry of Food to utilize the separated corpuscles for the manufacture of black pudding to be taken by mouth.

Because the study of nutrition throws light on the human condition, it is inevitable that nutritionists feel moved to allow their hearts and consciences to be influenced by what the evidence of their intellects brings to light. In Peru, the advent of industrialization and mining attracts peasants from the highlands of the interior to the slums of Lima where, as Dr. G. G. Graham of Baltimore observed, and showed to the Congress in a series of horrifying photographs, their children sicken and die of marasmus. Yet at the same time a developing fishing industry provides a flourishing export of fish flour. The adults who work in the copper mines and in the fish-flour factory share in the modest material prosperity, yet the young children suffer. Where, then, shall the nutritionist draw the line: at the scientific deduction that marasmus is a syndrome in infants resulting from lack of calories and protein? that the disease is aggravated by the export of fish rather than its distribution among the shanty dwellers of Lima? or that a more vigorous export

drive combined with an increase in industrialization would further enrich the nation and enable more peasants to work for better wages in the towns rather than suffer the hardships of a primitive agrarian existence?

The proceedings of the International Congress showed quite clearly that nutritionists now recognize that nutrition is something more than a scientific speciality. Dr. Walter Kraak of Bonn chose as the title of his paper, "Co-ordination of Research, Economics, Technology and Public Sanitation as a Basis for Proper Nutrition". Prof. K. Breirem of Vollebekk, Norway, in introducing a session to discuss problems of world nutrition in the future, quoted the aphorism that "nutrition is not a science but is a meeting place for scientists". But is this enough? By their recognition that economics, sociology, ethnology, anthropology—no one had the courage to mention the very Prince of Denmark himself, namely, politics—are germane to their studies, the nutritionists at Hamburg showed a welcome awareness of the implications of the problems with which they were trying to deal. But even if in the future they invite other kinds of scientists than those expert in human and animal nutrition to contribute to their congresses, will they succeed then in talking sense? Should such meetings be restricted only to scientists?

On the final day at Hamburg, Prof. H. Wilbrandt of Gottingen came to the heart of the matter. Scientific studies in underdeveloped countries have brought to light the causes of nutritional diseases and thus shown the means to cure and prevent them, selfless workers from international organizations have striven with devotion to aid, succour and teach the unfortunate. Nevertheless it is hard to deny that in too many instances the end result has been worse than the beginning. The introduction of many Western ideas—white bread, carbonated beverages, even canned milk—has done harm rather than good. Food gifts from rich nations, said Prof. Wilbrandt, are no real assistance to those who receive them. They keep the poor countries impoverished. The present policies are erroneous and lead to perdition. It is in those countries where people leave the land, abandon a policy of peasant agrarianism and embrace a philosophy of industrialization that agriculture becomes efficient and productive.

Nutritional scientists have no title to discuss economics, industrialization or such political and philosophical matters as whether in equity a country that indulges in the sentimental luxury of supporting an enormous population of unproductive cows and an even larger population of even less productive monkeys can rationally expect to receive large gifts of "surplus" wheat. But the fact that some at least of the nutritionists at Hamburg realized that this was so, that they recognized as windy platitudes the inevitable speeches about their goal being to banish all hunger from all the populations of the globe (even before breakfast), that they can point out the need for rational and informed discussion of the problem —these things justified the meeting at Hamburg and are an augury for better congresses in the future.

MAGNUS PYKE

REPORTS

ZOOPLANKTON SAMPLING

AT the symposium on zooplankton production organized by the International Council for the Exploration of the Sea (ICES) in Copenhagen in 1961 (ref. 1) a sub-committee was set up to look into the possibilities of standardization of zooplankton sampling. Similar aims were expressed by the Scientific Committee on Oceanic Research of the International Council of Scientific Unions (SCOR) and by the U.S. National Academy of Sciences Committee on Oceanography (NASCO), and it was obviously desirable that a single committee be asked to look into this question on an international basis. A joint committee was set up by ICES, SCOR and Unesco as three international bodies which would give other national committees, as well as NASCO, the opportunity to pass on the benefits of their experience through their membership of SCOR.

The first meeting of this committee was held in Paris in January 1964 under the chairmanship of Dr. J. H. Fraser, with Dr. G. Humphrey (the past president of SCOR), Dr. T. Parsons (then of the Office of Oceanography, Unesco) and Professor J. Frey (then chairman of the ICES Plankton Committee). Because zooplankton includes such a variety of organisms, it was obviously impossible to recommend a single apparatus and it was decided to set up four working parties to deal with organisms in four arbitrarily chosen size ranges.

Working party 1 was asked to deal with the microzooplankton, at present sampled by water-bottle, very fine meshed nets, or filtered from pumped supplies. Working party 2 was given the next size range, at present sampled by a great range of techniques including the almost traditional use of a No. 3 mesh. Working party 3 was asked to consider the plankton often sampled by stramin and other coarse meshed nets, while working party 4 was asked to deal with the fast moving macroplankton, including euphausids and small fish.

The working parties were given two years to report and could not themselves undertake research. Working parties 1 and 4 completed their work by correspondence only; working party 2 met in Villefranche in September 1965 immediately before the ICES and IBP meetings in Rome. Working party 3 met in Sydney in February 1966.

Working party 1 assumed an arbitrary upper limit of 200μ for the organisms dealt with, as this had been selected by working party 2 as its lower limit. In its report, emphasis was placed on the need for more knowledge of the microzooplankton and its importance in energy transfer. Existing methods were reviewed and a majority of the group preferred the use of a 10-l. water bottle to give a significant sample of forms up to about 150μ; the disadvantage of having to take many samples to cover different depth ranges was also emphasized. Organisms 75–200μ, especially the more sparsely distributed species, might best be sampled by a fine-meshed net.

Methods of estimating biomass call for standardization, but the basic difficulties of separating dead from living matter and phytoplankton from zooplankton seem as yet to forestall any completely satisfactory method. Uniformity of approach to the problem of production must also be sought and active investigation into these fields is recommended.

Working party 2 decided that their most hopeful approach towards standardization would be to design a new but simple net aimed at giving an assessment of the biomass of the plankton from 200μ upwards to about 10 mm. A prototype design was agreed for testing during the symposium at Sydney, and as a result of these tests and further experimental trials by Dr. Paul Smith of the Fishery Oceanography Centre of the U.S. Fish and Wildlife Service some modifications were made. The net being considered has a mouth opening 57 cm in diameter (0·25 m^2) and a filtration area of 6 : 1 with nylon 'Nytal *P*7' basket weave, which has a mesh aperture of 200μ and a 45 per cent porosity (ratio of mesh aperture to total area). It has a cylindrical section of 95 cm followed by a conical section with a side length of 166 cm. The turbulence of the water flow which results from the ring creates an undulating movement of the cylindrical part which tends to clean it and gives it a superior sustained filtering efficiency. The nylon is attached to the ring by a canvas band of 10 cm width and there is also a 10 cm canvas band 57 cm below the upper canvas band where a throttling line can be fitted for closing the net. The ring is 57 cm

internal diameter, 1·5 cm diameter thickness with three attached eyelets for the bridles and rope lead attachments. The three bridles are each 57 cm in length attached to a swivel, and the nylon rope leads are to take a 25 kg weight under normal usage, though a 40 kg weight is desirable under conditions when the wire angle would exceed 25°. It is recommended that a flowmeter (*TSK* or equivalent) should be fitted from three points on the ring and accurately centred 14·25 cm from the rim. The codend should be a light-weight bucket (7·5 cm diameter) of polyvinyl chloride or brass, fitted with windows of the same mesh as the net, and with a volume of 150–200 c.c. (when plankton is required alive a volume of 500 c.c. is preferable), but for use in very rich waters a bag of the same mesh as the net is more convenient. The filtration efficiency of this net is 94 per cent. It should be used vertically, lowered at 60 m/min and hauled 45 m/min which should give a towing duration of 4·5 min for 200 m water column during which time clogging should not normally reduce the efficiency of the net to less than 85 per cent. Where possible a second flowmeter should be attached outside the rim to give an indication of efficiency, and if this is less than 85 per cent the haul should not be considered as quantitatively representative.

Working party 2 also recommends taking two simultaneous samples, or splitting the sample into two halves, one for biomass determination by the Lovegrove method[2,3] and one for counting and taxonomic analysis. It also recommends more research into net design, water flow, plankton behaviour and patchiness, and on net material. The development of telemetering depth-flowmeters, and electrical methods of opening and closing nets, are desirable as well as research into the effect of shock waves arising from the ship and noise on plankton sampling.

Working party 3 considered that an encased high-speed sampler would be the best sampler for their size range of organisms, but that none of current design was near enough to the ideal. It recommended further research to produce a suitable design and suggest the features to be considered as ideals, although it must be realized that some compromises may be necessary to make it a workable and practical design. In the meantime it recommends a net with a mouth opening of 1 m^2, the net made of monofilament nylon of 1 mm mesh aperture having a cylindrical forward part 57 cm and a conical after part 200 cm in length and strengthened with six longitudinal tapes not more than 2 cm wide. It should have a throat of sailcloth not more than 12 cm wide wrapped around the ring, which should be of galvanized tubing of about 2 cm outside diameter and with three bridles equal in length to the mouth diameter. A flowmeter should be fitted in the mouth area 25 cm from the ring and the collecting bucket should be light in weight. This net should be towed at 2–3 knots using a sinker of 40 kg or an equally efficient depressor. The organisms sampled by this net would overlap those taken by the net designed by working party 2 mainly for biomass determination. Use of the 1 mm mesh advocated by working party 3 has the advantage that it is possible to filter far greater quantities of water and so sample the larger species which are usually less abundant. These will be retained relatively free from contamination by those great quantities of small organisms which interfere with sorting and which by adhering during fixation make taxonomic separation difficult. The report from this working party also recommends further research to find the best means of telemetering information from the sampler to the surface and telemetering control signals to the sampler.

Working party 4 considered that the organisms in its size range (about 2–20 cm) would be best termed micronekton rather than macroplankton as this would reduce confusion with the range considered by working party 3. Gelatinous organisms and other animals greater than 10 cm will occur in the catches and these must be considered separately from the main sample. The working party considered that of the methods available only one sampler has widespread use—the Isaacs–Kidd Midwater Trawl—though it notes that as there is no method of measuring the volume of water filtered it is only semi-quantitative. The net should be large and the 6 ft. or 10 ft. net (that is, depressor spread) should be used according to the available shipboard facilities. The mesh should be 0·5 in. (12·5 mm) stretched nylon supported within an outer net of about 2·5 in. (6·5 cm) knot to knot. The use of mixed or graded meshes is deprecated even though the catch is maintained in better condition if the codend is preceded by a short length of 3 mm mesh (any resulting small organisms in the catch could be disregarded).

The speed of the ship should be maintained at 3 knots, wire should be paid out at 40 metres/min, hauled at 40 metres/min for oblique tows or 60 for horizontal tows. Oblique hauls should sample 200–0 m depth and for thorough depth sampling by horizontal tows sampling should be at 50 m intervals to 1,000 mm and 250 mm intervals beyond. The use of a depth-time recorder or depth telemeter is a prerequisite of midwater sampling because accurate knowledge of the depth of fishing is essential to a proper interpretation of the data. A flowmeter should be used to measure the relative length of tow.

The reports of all four working parties are to be collated into one which will be published in due course as a Unesco monograph.

OBITUARIES

Patrick B. Kennedy

PATRICK BRENDAN KENNEDY, first professor of mathematics at the University of York, died suddenly on June 8, 1966, aged only 37. He was born at Cork and educated there at North Monastery and later University College. After obtaining an M.A. at Cork he went to the then University College of the South-west at Exeter to study the theory of functions of a complex variable, and this subject remained one of his main interests. His Ph.D. thesis was stimulated by a conjecture of M. H. Heins, which he disproved, and contained a discussion of the minimum growth of an integral function with k symptotic values together with counter-examples to show that all his theorems were the best possible. To construct these counter-examples he provided a method for approximating certain subharmonic functions by logarithms of integral functions which proved then and is now a most valuable tool. The distinction of this work was recognized when after a short period as assistant lecturer at Aberystwyth and lecturer at Cork he was appointed professor of mathematics at Cork in 1956. He was appointed to the chair at York in 1963.

Kennedy had a delightful Irish humour, which always made him charming company, but he was nevertheless an extremely serious person and drove himself hard. He took a strong personal interest in all his students. He found it hard to delegate work to his junior colleagues, feeling that they should not be overburdened with chores but should have the opportunity for their own researches. He was also keenly interested in all matters of education and had been a member of the teaching committee of the Mathematical Association. At the time of his death he was writing two books, conducting the first degree examinations at York and also acting as external examiner at Cork. He is survived by his wife, whom he married in 1954, and three children.

W. K. HAYMAN

IDENTIFICATION OF RADIO GALAXIES AND QUASI-STELLAR OBJECTS

By J. G. BOLTON
C.S.I.R.O. Radiophysics Laboratory, Sydney, Australia

ABOUT 2,000 radio sources between declinations +20° and −90° have been catalogued during the past four years with the 210 ft. telescope at Parkes. The finding survey for the catalogue was made at a frequency of 408 Mc/s and additional observations were made of most sources at 1,410 and 2,650 Mc/s. The nominal lower limit of flux density for most of the survey was 2·5 flux units (10^{-26} W m^{-2} $(c/s)^{-1}$) and the accuracy of the source positions is estimated to be ±1 minute of arc. More precise positions (±12 seconds of arc) have been determined for 640 sources with flux densities greater than 1·6 flux units at 1,410 Mc/s. A search of the *Palomar Sky Survey* prints in the area between declinations 20° and −33° which is common to both the *Sky Survey* and the *Parkes Catalogue* has yielded about 400 identifications. The various zones of the *Catalogue*[1], the precise positions[2] and details of the identifications[3] are at present being published in the *Australian Journal of Physics*.

So far as identifications are concerned, the statistically most complete sample is that of 383 sources between declinations 20° and −30° for which accurate positions are available. Their distribution in celestial co-ordinates and the identification status of each source is shown in Fig. 1. All the sources shown on this diagram are believed to be extragalactic. In the area inside the dotted line, the sources are partly of galactic origin and the fraction of sources which can be identified is reduced by obscuration within the Galaxy. 143, or 38 per cent, of the 383 sources can be identified with galaxies and 100, or 26 per cent, with quasi-stellar objects. About 60 per cent of the quasi-stellar objects have been confirmed by optical investigations. Somewhat similar results have been obtained by Wyndham[4] from an investigation of 300 sources from the revised *3C* catalogue with flux densities greater than 9 flux units at 178 Mc/s. Of the 242 identifications in the present sample, sixty are either previously well known identifications, or have been independently identified by Wyndham. Wyndham's ratio of quasi-stellar objects to galaxies is somewhat lower than that of the present results; this probably arises from the difference in the survey frequencies used in the *3C* and *Parkes Catalogues* and the difference in radio spectra for quasi-stellar objects and galaxies.

This difference between the radio spectra of quasi-stellar objects and galaxies was first noted by A. J. Shimmins of this laboratory (private communication). It is illustrated in Fig. 2, which shows the distribution of the quasi-stellar objects, the galaxies and the unidentified sources in terms of the ratio of their flux densities at 1,410 and 2,650 Mc/s. Most of the galaxies lie well to the right of the line at a ratio of 1·6, whereas the peak of the distribution of quasi-stellar objects is to the left. Thus, the quasi-stellar objects can be distinguished from galaxies by their high-frequency spectra and, on this basis, Fig. 2*c*

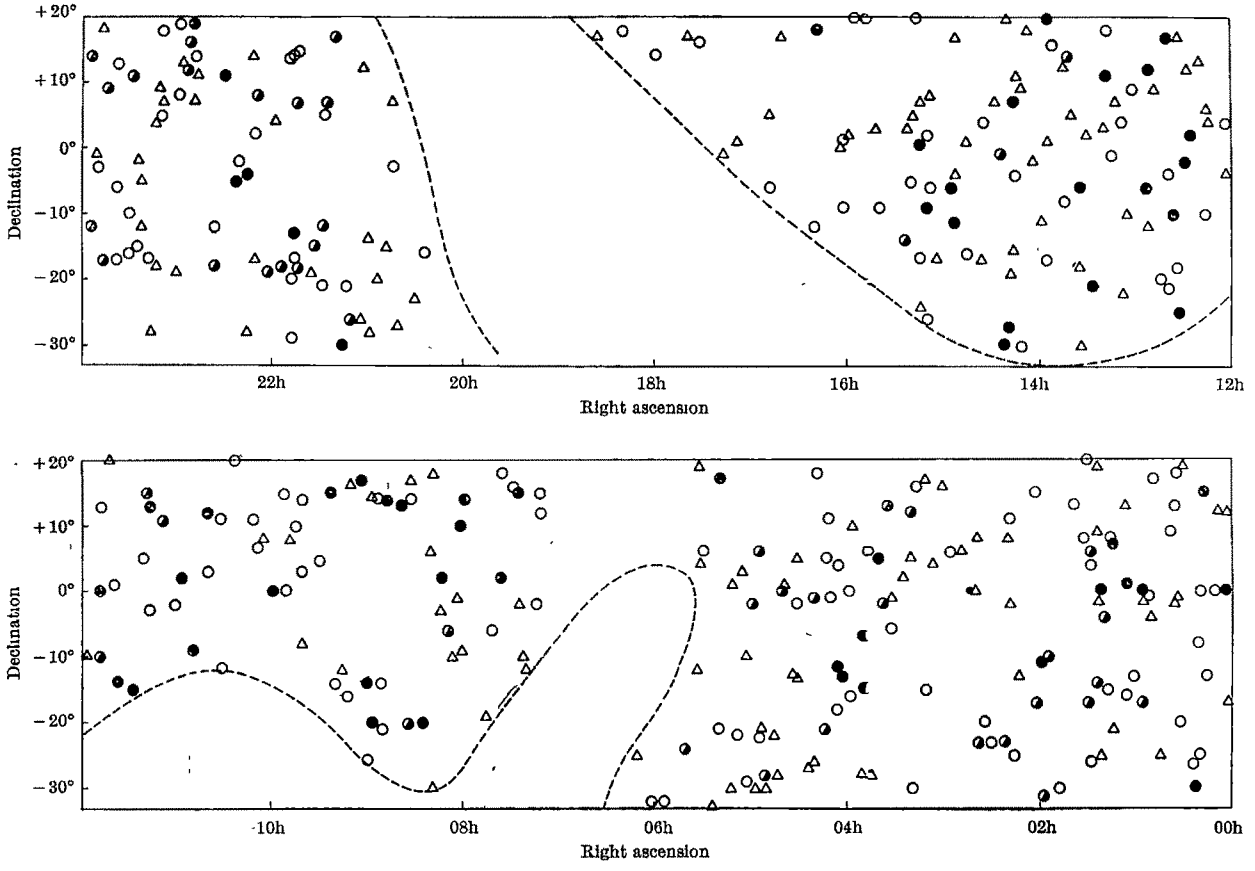

Fig. 1. Distribution of 383 radio sources between declinations 20° and −30° for which precise positions are available. ○, Unidentified sources; △, galaxies; ●, confirmed quasi-stellar objects; ◑, possible quasi-stellar objects. Dashed line encloses area containing a fraction of galactic sources or regions of obscuration.

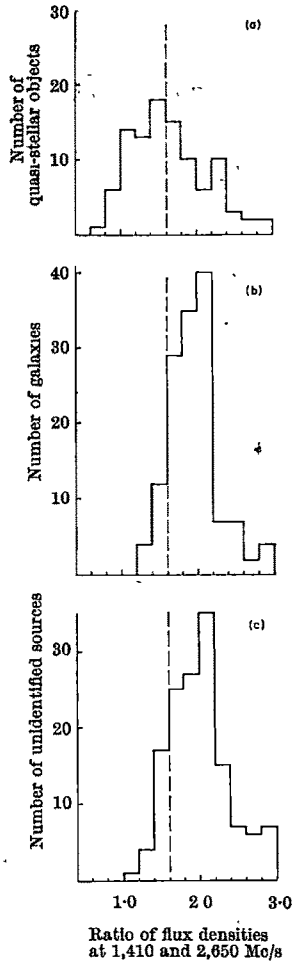

Fig. 2. Histograms of the number of sources with a given ratio of flux density at 1,410 and 2,650 Mc/s for: (*a*) quasi-stellar objects, (*b*) galaxies; (*c*) unidentified sources.

strongly suggests that the majority of unidentified sources are galaxies which are presumably fainter than the plate limit of the *Sky Survey*. Two further arguments may be advanced to support this result.

The first depends on the distribution of radio and optical magnitudes for the identified sources shown in Fig. 3, in which the radio magnitude scale at 1,410 Mc/s has been adopted such that 1 flux unit is equivalent to a radio magnitude of 10·5. Most of the optical magnitudes were estimated by comparison of their images on the *Sky Survey* plates with those of objects for which photometric magnitudes are available. For faint objects these estimated magnitudes probably have quite large errors but not of sufficient extent radically to alter Fig. 3. Fig. 3*d* for the galaxies shows the well-known large range in optical magnitudes corresponding to a small range in radio magnitudes. The distribution is markedly skew and strongly reflects the effect of the plate limit of the *Sky Survey*. The distributions for quasi-stellar objects show a much closer relationship between optical and radio magnitudes: there is no suggestion of a cut-off owing to plate limit, which would probably be at least one magnitude fainter for stellar objects than for galaxies. The sharp cut-off in the magnitude distribution for the galaxies suggests that the unidentified sources may well be galaxies beyond the *Sky Survey* plate limit. The magnitude distribution for quasi-stellar objects suggests that the identifications with quasi-stellar objects are essentially complete for the present sample, and that quasi-stellar objects between the nineteenth magnitude and the plate limit would be found among radio sources which are fainter than those of the present sample.

A second argument is provided by observations for interplanetary scintillations of about 200 of this sample of sources (due to R. D. Ekers of this laboratory). Such scintillation is an indication of the small angular size of a source (2 sec of arc or less). Ekers found that more than 50 per cent of the suggested quasi-stellar objects scintillate, whereas only 20 per cent of the galaxies fainter than the seventeenth magnitude do so. He found that only 25 per cent of the unidentified sources scintillate and, on the assumption that they are, in general, more distant than identified sources of the same class, his results strongly suggest that they are galaxies rather than quasi-stellar objects.

Source Counts. The anomaly of "too many faint sources" in the counts of radio sources with flux density is now well established. The slope of the graph of the logarithm of the number of sources (N) with a flux density greater than S against this value of log S is approximately $-1{\cdot}8$, compared with an expected slope of $-1{\cdot}5$ for a uniform distribution of sources in a Euclidean universe. This result has been interpreted either as indicating an evolving universe in which radio sources were more numerous or intrinsically brighter in its earlier history, or in terms of a local deficiency in a fraction of the population, which is presumed to be of galactic origin. Véron[5] and Longair[6] have independently pointed out that the slope of the log N–log S curve is significantly different for different classes of sources. They find the slope for galaxies is of the order of $-1{\cdot}5$, for quasi-stellar objects $-2{\cdot}2$, and even steeper for unidentified sources. The obvious inferences have been drawn—that the quasi-stellar objects and unidentified objects are responsible for the anomaly on the evolving universe model—or, for example, in a model by Sciama and Saslaw[7], that the unidentified sources and possibly some of the quasi-stellar objects for which red-shifts are not yet available, represent a galactic component.

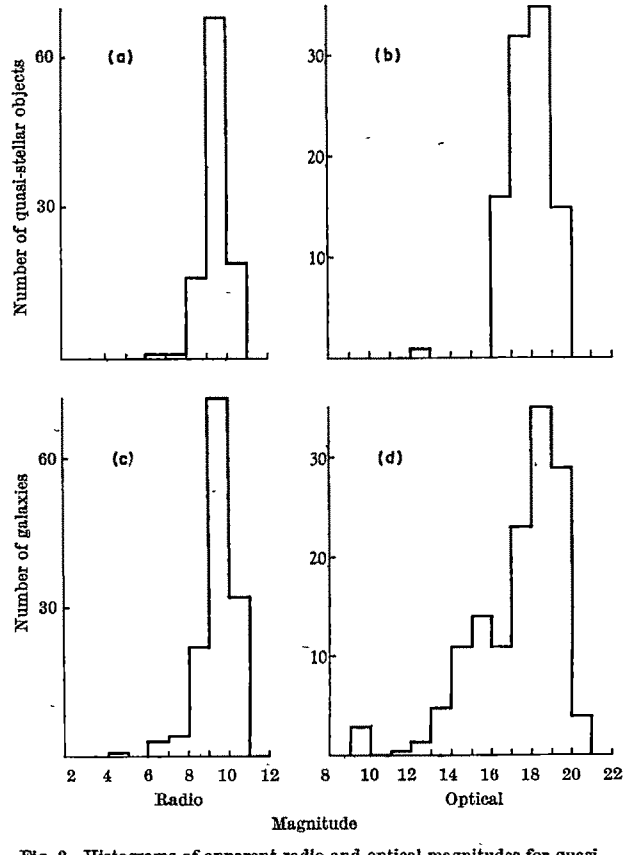

Fig. 3. Histograms of apparent radio and optical magnitudes for quasi-stellar objects and galaxies.

The present observations substantiate the results of Véron and Longair. The counts for the three classes at 1,410 and 2,650 Mc/s are shown in Fig. 4*a*, *b* and *c*. The differences between the slopes are not as extreme as those of Véron and Longair, possibly because of the larger number of samples involved, but they are nevertheless quite pronounced. The log N–log S relationship for galaxies does not, in fact, have a constant slope but is markedly flatter towards the faint end. Such an effect would result from the cut-off imposed on identifications of galaxies by the plate limit of the *Sky Survey*, for the fraction of identifications possible will decrease with the flux density. If the previous deduction that the unidentified sources are predominantly galaxies is correct, then these sources should be included with the galaxies in the count. The log N–log S relationship for galaxies and unidentified sources is shown in Fig. 3*d*, where its slope can be seen to be indistinguishable from that of the quasi-stellar objects. It will be seen that the log N–log S slope for the quasi-stellar objects is slightly flatter at 2,650 Mc/s than at 1,410 Mc/s. No significance should be attached to this result; it arises from the high fraction of flat spectrum sources among the quasi-stellar objects, and the selection criteria for the source sample. The galaxy counts do not show this effect, as the fraction of flat-spectrum sources among them is negligible.

The result that the modified log N–log S slope for galaxies is the same as that for quasi-stellar objects is perhaps not surprising for, if the red-shifts of the quasi-stellar objects are cosmological, the quasi-stellar objects and galaxies in the present sample span much the same volume of space. Most of the sources under consideration have

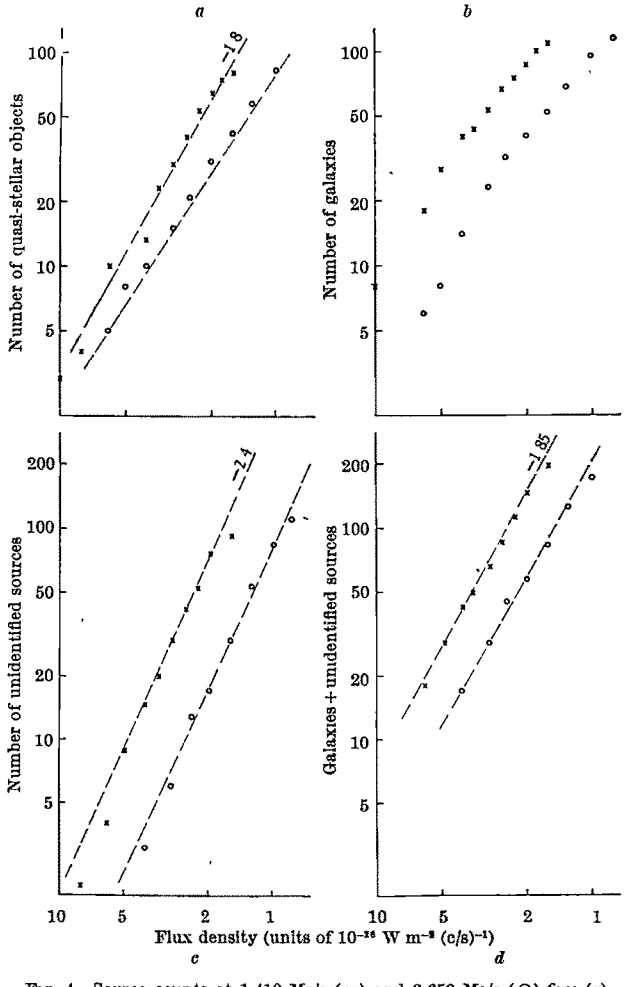

Fig. 4. Source counts at 1,410 Mc/s (×) and 2,650 Mc/s (○) for: (*a*) quasi-stellar objects; (*b*) galaxies, (*c*) unidentified sources, and (*d*) composite of galaxies and unidentified sources.

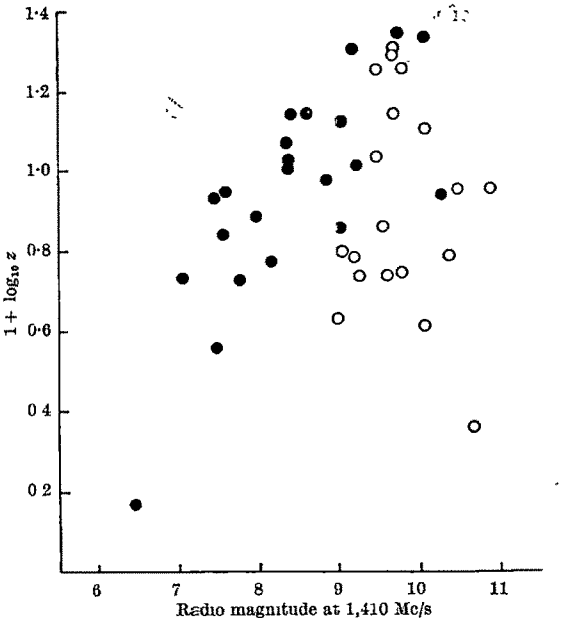

Fig. 5. Radio magnitude–red-shift diagram for quasi-stellar objects. ●, Objects with flat or relatively flat spectra; ○, objects with steep radio spectra.

apparent radio magnitudes between 9 and 10. In this range seventy-eight sources can be identified with galaxies and eighty are unidentified. A few of the latter may be faint or unrecognized quasi-stellar objects and some are probably N- type or compact galaxies above plate limit—which are difficult to distinguish from stars on the *Sky Survey* prints. However, at least fifty are probably galaxies beyond plate limit. These will have absolute radio magnitudes equal to or brighter than $M_r = -32$. The exact $M_r = -32$ cannot be determined, but it would certainly extend to form of the luminosity distribution beyond $M_r = -34$, because objects of this luminosity are known to exist (for example, Cygnus-*A* and 3*C* 295). Galaxies in this range will have distance moduli between 41·5 and 43·5, and the red-shifts of the most distant will be well in excess of unity. The similarity of the log N–log S for the galaxies and quasi-stellar objects within the same range of red-shifts may indicate a parallel evolutionary development.

Red-shift—Magnitude Relation for Quasi-stellar Objects. So far in this article it has been assumed that the red-shifts of the quasi-stellar objects are cosmological in origin. A number of alternative suggestions have been made to overcome difficulties associated with their energy supply and incompatibilities between their angular diameters and short period light variations. However, no really insurmountable objections to a cosmological origin have been raised, and the alternative hypotheses appear to provoke greater difficulties than they aim to overcome.

Hoyle and Burbidge[8] have recently questioned the cosmological red-shift on new grounds. They point out that there is no relationship between the red-shift and radio magnitude at low frequencies (178 Mc/s), and that even the relationship between red-shift and optical magnitude appears to be simply a scatter diagram. However, such a result does not necessarily vitiate a cosmological red-shift; it may merely be an indication of a large dispersion in the relevant absolute luminosities. To obtain a reasonable relationship demands an intrinsic property which is comparatively constant, as is the absolute optical magnitude for the radio galaxies. The large variations in the light output of some of the quasi-stellar objects would suggest that the optical magnitude is not such a property. About half the objects considered by Hoyle and Burbidge have fairly steep spectra, and

quite a few of this class of quasi-stellar objects are known to have components of considerable angular and presumably linear size. Such components may be the results of singular events, and similar to the large physical components of radio galaxies—for which there is certainly a very large range in intrinsic luminosity and a correspondingly large scatter in their radio magnitude–red-shift diagram. It is possible that the radio emission from quasi-stellar objects with flat radio spectra, which might result from a continuous process in a small physical volume, could be a better indicator of intrinsic luminosity. In Fig. 5 the relationship between the radio magnitude at 1,410 Mc/s and the red-shift is shown, with different symbols for the objects with relatively flat and steep spectra. While there is no very distinct relationship, the scatter for the flat-spectrum sources is considerably lower than that in either of the diagrams given by Hoyle and Burbidge. There is a suggestion that radio spectra might be useful in assigning a luminosity classification, and that a search for objects with very large red-shifts could be most successful among faint radio sources with flat spectra.

I thank many of my colleagues at the Radiophysics Laboratory who provided the basic data used in this investigation, particularly Dr. Margaret Clarke and Mrs. Jennifer Ekers for their work on identifications. I also thank Dr. T. D. Kinman of the Lick Observatory for providing optical confirmation and accurate optical positions of many of the southern quasi-stellar objects, and Dr. Margaret Burbidge for providing red-shift data in advance of publication.

RESOLUTION OF X-RAY SOURCES AT LOW GALACTIC LONGITUDE

By Dr. PHILIP C. FISHER, Dr. WILLARD C. JORDAN, ARTHUR J. MEYEROTT, LOREN W. ACTON and DOUGLAS T. ROETHIG

Lockheed Palo Alto Research Laboratories, Palo Alto, California

The second of two rockets instrumented primarily for locating celestial X-ray sources at low galactic latitude ($|b^{II}| < 20°$) was flown on September 30, 1965. During 1964, three different groups[1–3] examined most of the longitude interval $330° < l^{II} < 25°$ and a number of X-ray sources were located. In addition to some discrete sources, a significant residue of counts was found above background[1] which did not appear to be associated with any of the discrete sources. Part of the 1965 flight was arranged to determine if these residual counts represented an extended source or a number of individual sources. It was also hoped that a better determination of the galactic latitude of the sources already observed might provide some indication of their relative position within the Galaxy.

An *Aerobee* rocket fitted with a roll-stabilized attitude control system (ACS) was used and flown from the White Sands Missile Range. The ACS was programmed such that two differently oriented X-ray detectors could make two short scans approximately parallel to the galactic equator. Owing to a failure in the ACS, a third scan normal to the galactic equator was not carried out. Gas proportional counters with berylium windows were used to measure the energy of each X-ray detected, while photometers sensitive to visible light were used to obtain information concerning stellar aspect. Pulse heights of individual events in the X-ray detectors, detector scan rates, and stellar signals from the aspect photometers were all telemetered to the ground. The intermittent behaviour of the signals from the optical photometers (believed to be related to a visible glow observed around the rocket[4]) has meant that information is of little use for the results presented here. It should be noted that a small part of the sky near the galactic centre was not observed on the 1965 flight owing to the presence of the Moon, which lay at $\alpha = 17h\ 22m$, $\delta = -24{\cdot}6°$ and passed through the field of view of detector *A* near 150·5 sec after the launching.

One major difference between the 1964 and 1965 flights was that the fields of view of the 1965 detectors were reduced to a half and a fifth that of the field of detector *C* used in 1964. Table 1 indicates the characteristics of the three detectors. Counter *A* had a detection efficiency similar to that of the counter used in obtaining the 1964 data, while counter *B* was more sensitive above 5 keV because of a higher filling pressure and because xenon as well as argon and methane were used for the filling gas.

Fig. 1 presents the observed counting rate as a function of time for segments of the two flights; the 1965 data have been corrected for the dead time of the counter's electronics—this correction ranges from about 15 per cent when no discrete source was within the field of view to about 50 per cent for the peak rates seen at 138 sec and 152 sec after launch. No correction of the 1964 data was necessary. The rockets were scanning at rates of 2·03, 1·08, and 0·58 degrees/sec while the data of detectors *C*, *A* and *B* respectively were being acquired. Therefore the time scales of the data have been adjusted for these different scan rates in order to show the relative galactic longitude of the various sources that were observed. The discussion of how the high count regions were correlated with position on the celestial sphere, and so with the galactic longitude scale given in Fig. 1, will be presented later. The data for detector *A* given in Fig. 1 were acquired at about the same galactic latitude as the data for detector *C*. While six high count rate regions were suggested by the 1964 data, on at least seven occasions during the first 1965 scan the signal for counter *A* indicates the presence of an X-ray source. Another significant difference in the Fig. 1 data occurs near $l^{II} = 0°$, corresponding to the

Table 1. X-Ray Detector Characteristics for Data presented in Fig. 1

Detector	Flight date	Effective window area (cm²)	Field of view* (degrees)	Approximate energy interval (keV)	Counter filling gas
C	Oct. 1, 1964	263	2·9 × 26·5	4–8	90% argon, 10% methane
A	Sept. 30, 1965	195	1·8, × 16·7	2–9	90% argon, 10% methane
B	Sept. 30, 1965	235	1·7 × 7·4	3–11	69·5% argon, 20% xenon, 10% methane, 0·5% helium

* Full width at half maximum sensitivity.

time interval of detector A of 148 sec to 152 sec after the launching. It may well be that the major part of this difference is the result of the quite different sizes and slightly different orientations of the field of view of the two detectors. For example, one of the 1964 sources[1] may lie outside the field of view of detector A, or several of the 1964 sources[1-3] may have been observed simultaneously (despite the improved angular resolution of the detectors used) on the more recent flight. A decrease in the absolute flux of one of the 1964 sources cannot be ruled out. In addition to these differences, new X-ray sources were observed by detector A near 160 sec and 129 sec after the launching. The latter source was so close to the horizon of the 1964 flight that it may not have been observed at that time. Although the long dimension of field of view of counter B was only half that of the field of detector A, on this first scan detector B observed all but the weakest source seen by detector A. Except for this source, the first scan data from detector B show count rate variations similar in time and amplitude to those of detector A. There is a possibility that detector B saw simultaneously the first two sources which came into view of detector A at 130·5 sec after the launching.

The data given in Fig. 1 for detector B were acquired during the second scan of the 1965 flight which was carried out at about a 5° lower latitude than that used in obtaining the detector A and C data shown. Considering the scan rate and the counter background, the highest detection sensitivity of the experiment (about 0·1 photons cm^{-2} sec^{-1}) was attained while the data given in Fig. 1 for detector B were being obtained. Only two sources were observed by detector B on this scan. Although no unambiguous location of the X-ray source near 218 sec has been obtained, the other source at 207·4 sec after the launching seems to be the same as that observed by detector A near 152 sec.

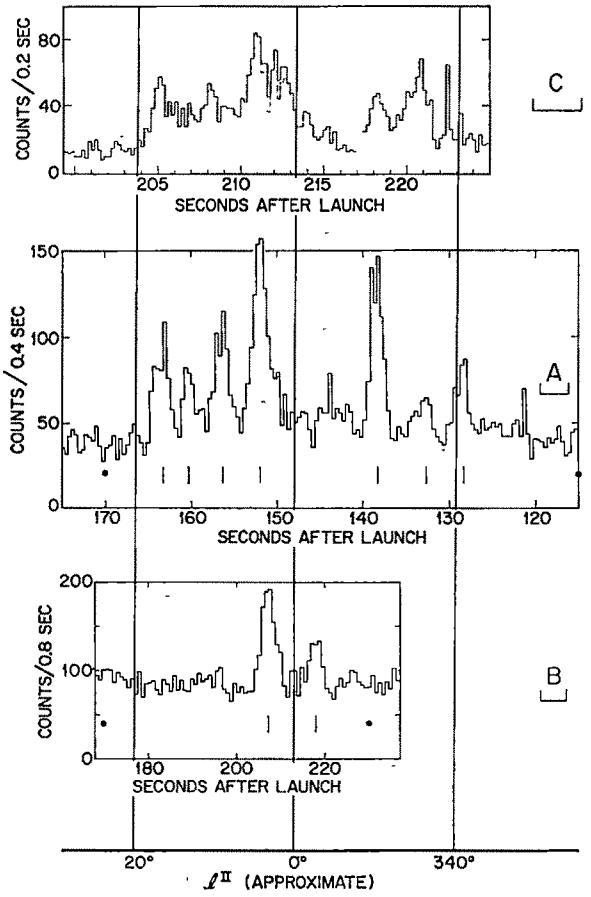

Fig. 1. Counts observed during two rocket flights, while scanning in longitude near the galactic equator. Letters at the right of the figure denote which detector the data were derived from, and the line segments under these letters indicate the time required for a point source to pass completely through the narrow dimension of the field of view of the detector. The time intervals between the black dots shown with the data of detectors A and B indicate the duration of the two 1965 scans. Dotted lines in the detector C data near 212 sec show the count rate anticipated after subtraction of effects from the brightest source in Scorpius which lay near the edge of the field of view of detector C at this time.

The regions of higher count rate observed by detectors A and B have been correlated on the basis of the collimator orientations on the rocket and on the assumption that no important spectral differences existed for a given (postulated) source. Although the statistics are poor, this assumption seems valid as no striking spectral differences appear in the data of the two counters for any of the seven sources. The correlations lead to a determination of: (1) the distance and direction of each of the given sources from the scan path; (2) the distances between sources measured along the scan path; (3) the strength in counts cm^{-2} sec^{-1} of each source observed. Relative position along the scan path can be computed from the elapsed time between observation of X-ray sources. For the 148–165-sec time interval of the data for detector A, no action of the ACS occurred which would have affected the position of the detector along the scan path. Consequently, the various points on the 1965 grid of relative positions for this interval are known to about $\pm 0{\cdot}6°$ along the scan path, while an error of about $\pm 1°$ is appropriate for the position of a source off the scan path.

The grid of relative positions from the 1965 experiment can be oriented on the celestial sphere by assuming the scan paths of the detectors are those prescribed by the roll-stabilized ACS. This assumption makes it possible to make some detailed correlations between the high count regions of the two flights. The data of detector C from the 1964 flight were supplemented by information on the galactic latitude of *SCO XR*-3[2] and *SCO X*-2[3]. Fig. 2 presents the result of this correlation. The heavy diagonal line indicates the galactic equator while the lighter long diagonal lines indicate the scan path of the centre of the field of view of the two 1965 detectors. Although the scan path of detector C is not shown, it lay slightly below the galactic equator. The longitudes of the sources observed[1] in 1964 are indicated by the shaded swaths nearly perpendicular to the galactic equator. The inter-comparisons of X-ray data indicate a lateral shift of about 1°, and a skew of about 1°, of the detector's actual scan path as compared with the path originally prescribed for the ACS. This shifted path has been used in Fig. 2. Such a shift is within the nominal errors established for operation of the roll-stabilized ACS. The position of the scan path shown in Fig. 2 is believed to be known to within about $\pm 1°$, and this uncertainty provides the chief contribution to the error in source location indicated by the areas outlined. It is hoped that reduction of the optical aspect data will lead to an improvement in the determination of the location of the X-ray sources.

The positions and fluxes of the X-ray sources shown in Fig. 2 have been summarized in Table 2. In computing the counts cm^{-2} sec^{-1} of the sources observed by detector A, a background rate was used that was the average of the counts observed in the 121–126 and 166–171 sec time intervals. Although this rate indicates a significant residue of counts above background for the interval $350° < l^{II} < 0°$, the data seem inadequate to specify further the significance (or lack thereof) of these residual counts.

In only a few instances is the position information now available for the brighter X-ray sources adequate to attempt correlations with known features of the Galaxy. It does seem significant that source numbers 4 and 7 in Table 2 fall within $\pm 1{\cdot}5°$ of the nearby thermal radio sources M 8 and M 16. As noted earlier, the error in relative galactic longitude of these sources as seen by detector A is probably no more than $\pm 0{\cdot}6°$. The angles between count rate peaks which can be interpreted as the M 16 and M 8 signals on the first detector B scan (M 16 was too near the edge of the field of view to be detected on the second scan), and the angle between the M 8 and

* The measured count rates were corrected to that value which would have been observed if the source lay on the collimater's centreline.

† Remarks: (i) Source was below horizon in 1964 experiment (ref. 1) and lies within the large rectangular region of the 1965 experiment closest to the horizon in Fig. 2. Agreement in the count rates seen by detectors *A* and *B* suggests the X-ray source lies near $\alpha = 16$h 52m, $\delta = -46{\cdot}6°$. (ii) Air absorption has not yet been allowed for in the 1965 experiment, so this source's flux may or may not have decreased with time. The NRL position of *SCO XR*-3[2] has been given for this source and the comparisons of count rates were made assuming the X-ray source lies at this position. (iii) The NRL position of *SCO XR*-2[2] has been given for this source and the comparisons of count rates assuming the X-ray source lies at this position. (iv) The existence and/or location of this source is now in doubt. (v) As noted in the text, the observed X-rays may actually come from several sources. The most likely division of the observed flux seems to yield a bright source at the position given, and a fourfold weaker source near $\alpha = 17$h 37m, $\delta = -22\ 9°$. (vi) The *SGR XR*-2 source of NRL[2] has now been resolved into at least three different X-ray sources.

M 16 signals on the first and second scan of detector *A*, are all equal to within ±0·6° of values appropriate to their known differences[5] in position. Although *M* 8 and *M* 16 are not point sources in the radio or optical portions of the observable spectrum, Fig. 1 gives little or no indication that the (possibly) related X-ray sources are other than point sources. While the arguments concerning identification of *M* 8 and *M* 16 with X-ray sources seem sound, the only other bright thermal radio source in this range of longitudes, *M* 17, was apparently not observed.

To our knowledge, no theoretical estimates have been made for the X-ray flux associated with H II regions such as *M* 8, *M* 16 and *M* 17. However, if either their radio[6,7] or optical[7,8] fluxes are fitted to the spectral distribution of the Crab Nebula[9], X-ray fluxes are predicted which are comparable with or larger than those actually observed. Allen's short lists[10] of bright radio sources and diffuse nebulae suggest several other similar objects which might be examined for X-ray emission in order to provide greater confidence in the tentative identification of *M* 8 and *M* 16. For example, consider the X-ray sources in Cygnus observed by the Naval Research Laboratory (NRL) group[11]. Although *NGC* 7000 was omitted, both the Cygnus Loop and Cygnus *X* were noted in some of the data and on the most recent X-ray sky map of the NRL group[11]. The close proximity of the brightest radio portion of Cygnus *X* to the locations of Cygnus *A* and Cygnus *XR*-1 makes it quite difficult to correlate X-ray and radio sources in this region. However, *NGC* 7000 and Cygnus *X*, and the brightest radio emission region of the Cygnus Loop, all appear to lie quite close to high count locations noted by the NRL workers[11]. Such an association is at least consistent with the tentative *M* 8 and *M* 16 identifications. A further test and understanding of the hypothesis that bright and nearby radio sources may also be observable X-ray sources could be provided by examination of the Orion Nebula, *M* 42. Although the absence of dark globules in this object is an indication that it is fundamentally different[12] from *M* 8 and *M* 16, a similar naive fitting of radio and optical source strength with a Crab-Nebula-like spectrum suggests a measurable X-ray flux.

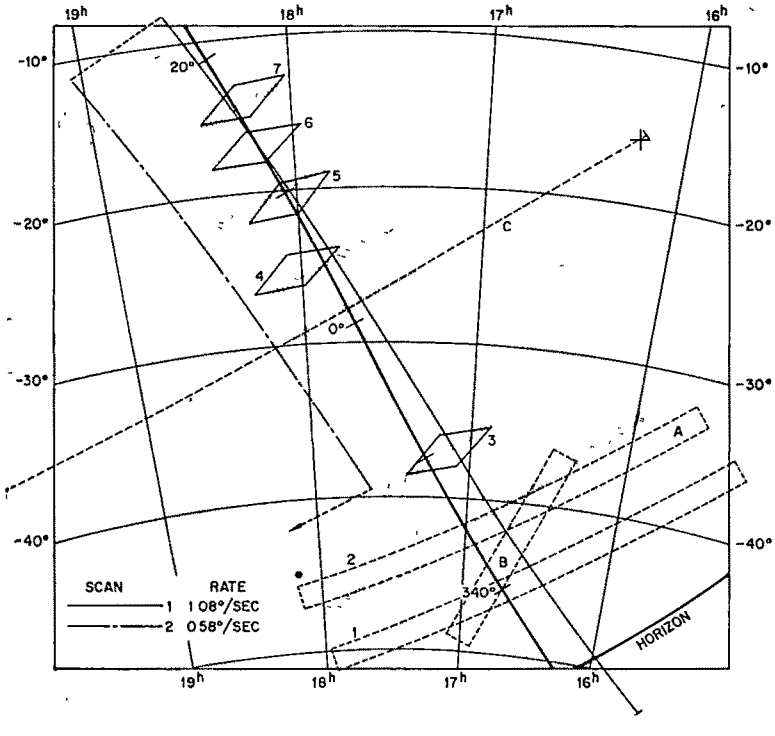

Fig. 2. Approximate positions of the brighter low-longitude sources observed on September 30, 1965. Co-ordinates of right ascension and declination are indicated as well as the galactic longitude. The outlined regions in which the sources are believed to lie are numbered as in Table 2. The large dotted rectangles near the lower right corner show the maximum latitude coverage and half the longitude coverage of the fields of view of detectors *A* and *B* when observing source Nos. 1 and 2 of Table 2. The orientation of these detectors relative to detector *C* of the 1964 experiment is apparent from the dotted line near the centre of the figure which shows the maximum galactic latitude coverage of detector *C*. The narrow shaded swaths indicate the central part of the regions where the 1964 measurements showed different sources must lie, the + at the upper right representing the position found in 1964 for the brightest X-ray source in Scorpius.

It appears to be significant that a fairly large fraction of the few radio sources which are nearby, intense, and have a relatively flat spectrum can be found in the vicinity of presently observed X-ray sources. These particular X-ray sources may well lie no more than several kiloparsecs away, those at low galactic longitude being no more distant than the Sagittarius arm of the Galaxy. While several new X-ray sources have been discovered and tentative associations with *M* 8 and *M* 16 have been made, an essential point of these data is the relatively large number of X-ray sources in a small area of sky. Although still more information (and possibly additional source positions) may yet be derived from the 1965

flight data, a significant further improvement of both angular resolution and detection sensitivity seems necessary before a more meaningful identification can be made of all the low longitude counts at present observed.

This work was carried out under contract with the National Aeronautics and Space Administration, and the Lockheed Independent Research Program.

RATIOS OF OXYGEN-18 : OXYGEN-16 IN PHOSPHATE AND CARBONATE FROM LIVING AND FOSSIL MARINE ORGANISMS

By Dr. A. LONGINELLI
Laboratorio Geologia Nucleare, Pisa, Italy

Earlier I reported[1] the results obtained by measuring the oxygen isotopic composition of phosphate from the shells of some living marine organisms. A summary of the technique used for the purification of the phosphate, the removal of the oxygen from the final product (bismuth *ortho*phosphate) by fluorination with bromine trifluoride, and its conversion to carbon dioxide for spectrometric measurement was also given.

This article reports the results of further measurements of oxygen isotopic composition carried out on shells of both living and fossil marine organisms together with some of the previous results. The main purpose of these measurements was to determine the relationship between growth temperature of shells and the abundance of oxygen-18 in their calcium phosphate. Such a relationship would help in measuring palaeotemperatures and in estimating the oxygen isotopic composition of ocean water during the past from the equation provided by Epstein *et al.*[2] for carbonates and a similar equation for phosphates. In both equations the unknowns are the growth temperature and the oxygen isotopic composition of the environmental water. In previous calculations of palaeotemperatures the oxygen isotopic composition of ocean water was assumed to have been equal to that of modern mean ocean water.

One problem in the establishment of a temperature scale is to obtain samples grown under controlled temperature conditions. This is very difficult in the case of phosphates owing to the small percentage of phosphate generally contained in the shells of marine organisms and to the difficulty of growing inarticulate brachiopods, which contain fairly large amounts of phosphate, in an aquarium. Crustaceans, the phosphate content of which is also high, do not seem to precipitate their phosphate in isotopic equilibrium[3]. The average growth temperature of the shells was calculated from the oxygen isotopic composition of the calcium carbonate of each shell, by means of Epstein *et al.*'s equation. It was assumed that both calcium phosphate and calcium carbonate were deposited contemporaneously. The results obtained were corrected for the isotopic effect of the environmental water. Eighteen specimens of fourteen different species of Lamellibranchiata, Gastropoda, Brachiopoda, Cirripedia, Cephalopoda and Echinodermata were measured.

The analytical results are given in the δ terminology, where δ is the deviation of the ratio of oxygen-18 : oxygen-16 in the sample from that of a working mass spectrometer standard :

$$R = (1 + \delta) R_{std}$$

The δ values are expressed in parts per thousand (mil) and reported against carbon dioxide obtained from *PDB*-1 standard by reaction with 100 per cent phosphoric acid and standard mean ocean water (SMOW) as defined by Craig[4].

The amount of phosphate (III) ion present in the shells ranged from traces to about 0·3 per cent. No investigations have as yet been made on the crystal chemistry of the phosphate. McConnell[5] showed that phosphate in *Lingula* shells is present as francolite (carbonate fluorapatite). In shells containing very small amounts of phosphate, however, it is possible that a significant percentage of the phosphate is in the organic matter of the shell itself (proteins). Some investigations are now being made on this subject.

The species measured, their locations and the results obtained are listed in Table 1. In Fig. 1 the oxygen

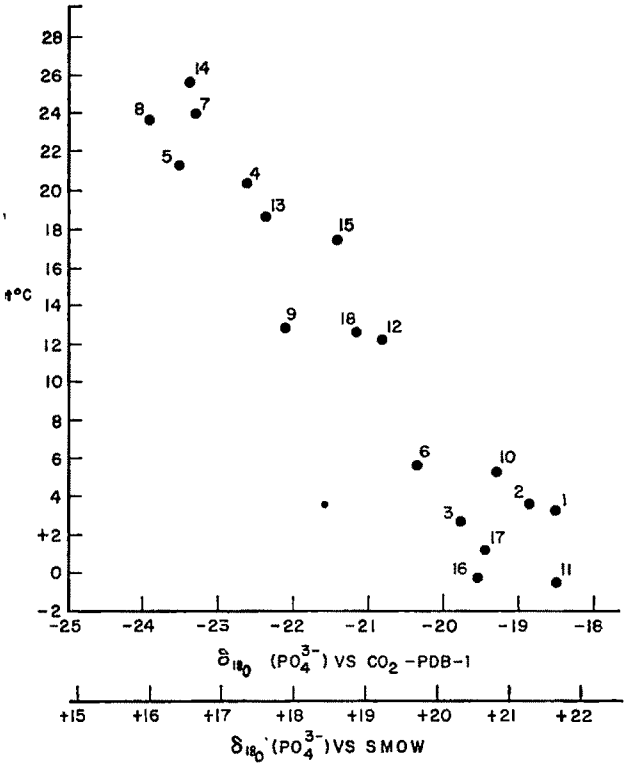

Fig. 1. Oxygen isotopic composition of phosphate from shells of living marine organisms versus their average growth temperature as calculated from carbonate δ's. The δ's are corrected for the effect of the isotopic composition of the environmental water. Numbers refer to Table 1.

isotopic composition of the phosphate is given against the average growth temperature of the shells as calculated from the oxygen isotopic composition of the carbonate. The dispersion of the points can be explained as arising from the error in the determination of carbonate δ's (standard deviations σ = ±0·1 per mil), the error in the evaluation of the correction for the H_2O isotopic effect (presumably between ±0·1 and ±0·2 per mil) and the error in the determination of the phosphate δ's (σ = ±0·18 per mil). The σ for phosphate δ's has been calculated from the results obtained on about 150 measurements.

Least-squares treatment of the data in Fig. 1 gave the following equation for the straight-line relationship between δ_{18O} (PO_4^{3-}) and t °C

$$t = -90{\cdot}0 - 4{\cdot}8\,(\delta_p - \delta_w)$$

where t is the temperature in °C, δ_p refers to the ratio of oxygen-18 : oxygen-16 in the phosphate (III) ion measured by the process described earlier[1], δ_w is the δ value of carbon dioxide equilibrated isotopically at 25·2° C with the environmental water, measured against the same mass spectrometer standard gas as used for the carbon dioxide obtained by conversion of the oxygen extracted from calcium phosphate. The calculated σ for this equation is ±2·70° C. A direct comparison of the coefficients in this equation with those in the carbon equation is difficult owing to the fact that the two equations are of different order; however, the slopes of these two equations are rather close. Plotting δ_{18O} (PO_4^{3-}) against δ_{18O} (CO_3^{2-}) (Fig. 2), the slope is found to be about 1·4. From the similarity in the slopes and from the precision one can obtain in measuring ($\delta_p - \delta_c$) (about ±0·3 per mil) the uncertainty with which the temperature t and the oxygen isotopic composition of the environmental water (δ_w) could be calculated for fossils containing both carbonate and phosphate is

$$t \pm 4{\cdot}5°\text{ C},\ \delta_w \pm 0{\cdot}8 \text{ per mil}$$

This temperature uncertainty is quite large for measuring the palaeotemperatures with reasonable accuracy; however, it is possible that the slope of the final equation will differ somewhat more from that of the carbonates. The uncertainty in the calculation of δ_w is small enough to make it possible to calculate whether or not there have been large variations of the oxygen isotopic composition of ocean water through geological time.

The oxygen isotopic composition of teeth of two fish was also measured in order to obtain information on the possibility of using fossil teeth for measurements of palaeotemperature. The following results were obtained:

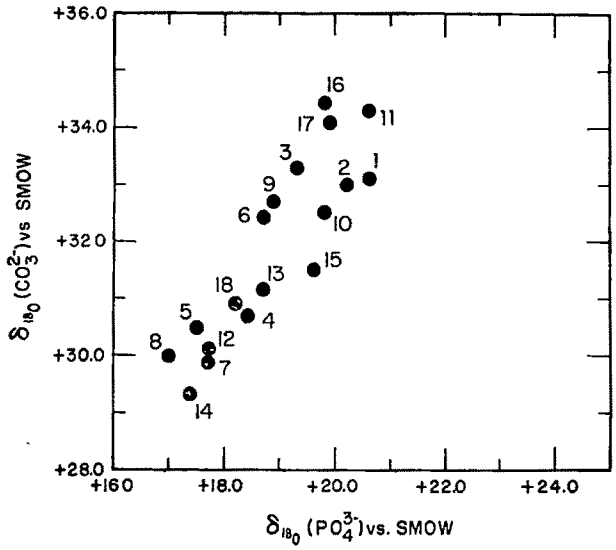

Fig. 2. Oxygen isotopic composition of co-existing carbonate and phosphate from shells of living marine organisms. Numbers refer to Table 1.

Oxyrina spallanzani (Adriatic Sea). Presumed temperature range 12°–23° C; average temperature recorded by the phosphate in the tooth 14·8° C.

Lagenorinchus albirostris (Northern Sea). Presumed temperature range 5°–17° C; average temperature recorded by the phosphate in the tooth 15·5° C.

Both the results are within the expected range of temperature even though they are near the limits.

On the basis of the results obtained it is possible to draw the following conclusions. (1) A general relationship exists between the temperature of deposition and the oxygen isotopic composition of phosphate in many marine invertebrates. From the good agreement shown by a considerable variety of organisms it can be assumed that in these cases the precipitation of phosphate occurs under isotopic equilibrium conditions. (2) The slopes of the phosphate and carbonate equations are rather close. On the basis of the results obtained so far it seems that isotopic palaeotemperatures cannot be measured with

reasonable accuracy by a carbonate–phosphate temperature scale. It should be possible, however, to obtain a good set of data on the possible existence of major variations of the oxygen isotopic composition of ocean water during geological time.

Measurements on Fossils

The oxygen isotopic composition of both carbonate and phosphate from some fossil marine organisms was measured. The fossils come mainly from Silurian, Carboniferous, Jurassic and Cretaceous formations in Belgium, Denmark, England, France, Germany, Greenland, Italy, The Netherlands, Scotland, Somaliland, the United States and the Soviet Union. Samples were mainly belemnites and pelecypods, together with a few brachiopods, rudists, crustaceans and fish teeth. The content of the phosphate (III) ion in these fossils ranges from about 0·05 up to about 34·0 per cent by weight. In species with very low phosphate contents two or three specimens from the same layer were processed together. The species measured, their locations, their ages, and the oxygen isotopic compositions of the phosphate (III) and carbonate (II) ions are given in Table 2. In Fig. 3 these phosphate δ's are plotted against the geological age attributed to each fossil.

A wide range of values was obtained. The most negative are those of Silurian and Carboniferous fossils. Among the Palaeozoic specimens there are freshwater and seawater fossils and a tooth of an unknown fish. All of them were very badly preserved, shells of *Obolus* had undergone recrystallization and the original material of the tooth was more than 50 per cent replaced by charcoal. The δ values of their phosphate are very close to one another and very negative. For *Obolus apollinis* the carbonate δ's (−8·2 versus *PDB*-1) are those of a carbonate which has almost completely re-equilibrated with ground (rain) water.

Among Jurassic fossils, belemnites have very large positive phosphate δ's which, on the tentative scale, correspond approximately to a temperature of about −10° C. Three pelecypods and one brachiopod show more negative δ values.

As regards Cretaceous fossils, a Lower Cretaceous belemnite is still as positive as Jurassic ones. A group of Middle Cretaceous fossils (chiefly pelecypods) gives δ values about midway between the most positive and the most negative. Several specimens from Upper Cretaceous formations (belemnites, a tooth of a fish and

Pseudoranenella) show rather scattered δ values which are again rather positive. The average δ value of this group corresponds approximately to a temperature of about +2° C. There also seems to be a tendency towards more negative δ values in younger specimens. In the case of fossils other than belemnites one is led to the conclusion that there is a general relationship between the ages of these fossils and the oxygen isotopic composition of their phosphate, their δ values becoming more and more negative with time. If this is correct, this can be caused by an isotopic exchange between the oxygen of the phosphate and the oxygen of ground waters. Despite the high bond energy between oxygen and phosphorus atoms, this exchange seems to reach a very high rate in Palaeozoic fossils. In fact, the freshwater fossil *Antraconauta phillipsii* (No. 32) shows the same oxygen isotopic composition as the sea-water fossils *Obolus* and *Lingula*.

If this is a correct interpretation of the values obtained from fossils other than belemnites, it can be concluded that for carbonates, because the bond energy of oxygen to carbon atoms is much lower than that of oxygen to phosphorus atoms, an isotopic exchange between carbonate and ground water took place in Mesozoic fossils.

The most difficult problem is to interpret the results obtained from belemnites. So far as I know, there are no natural fractionation processes which fossils normally undergo during the diagenesis of sediments which tend to enrich a fossil in oxygen-18. The fact that belemnites generally show very positive δ values could result from four different causes: (*a*) a biological fractionation effect; (*b*) the effect of some solid-state exchange (for example, between phosphate and carbonate); (*c*) the presence of secondary phosphate in the fossils; (*d*) a lesser exchange with ground water during diagenetic processes than observed in pelecypods and brachiopods.

The first hypothesis looks to be rather improbable as a biological fractionation effect would not adequately explain the difference between the δ values obtained from Jurassic and Upper Cretaceous belemnites. Moreover, modern Cephalopods, such as *Sepia officinalis*, seem to precipitate both their calcium carbonate and their calcium phosphate under isotopic equilibrium conditions. Finally, it must be remembered that a tooth from a fish (*Lamna appendiculata*) and a *Pseudoranenella* n. sp. from Upper Cretaceous show δ values very close to those of belemnites of the same age.

The possibility of some solid-state exchange should be rejected as it seems very difficult to explain how such a process could produce opposite fractionation effects in belemnites from those in pelecypods.

As regards the third hypothesis, it seems quite strange to obtain such positive δ's from phosphate of secondary origin. The natural exchange processes which fossils normally undergo during the diagenesis of sediments generally tend to deplete a fossil in oxygen-18. The same process can be supposed for phosphate on the basis of the results obtained from Palaeozoic specimens. However, the distribution of phosphorus in Jurassic and Cretaceous belemnites is now being studied by means of a microprobe. If the phosphate is of secondary origin, the phosphorus atoms should be concentrated along the apical canal and along the external surface, these areas being those in which an exchange or a replacement process can occur most easily. A study will also be made on the crystal chemistry of the phosphate in these belemnites.

The fourth hypothesis becomes acceptable on the basis of the following assumption. Considering the exchange surface, S (cm²), of a fossil and its mass, M (grams), the ratio S/M gives an idea of the probability of the presence of a significant rate of exchange between ground water and the fossil. For belemnites this ratio is about 1, while for pelecypods and brachiopods it reaches values of 10, 15 and even more. This means that the probability of an isotopic exchange of the oxygen between phosphate (or carbonate) and ground water is relatively low for belemnites and very high for brachiopods and pelecypods. This has been generally proved by measurements of palaeotemperature carried out by several authors on the carbonate of fossils. Pelecypods and brachiopods normally show more negative δ values than belemnites of the same age and from the same area. This is even observed in Upper Cretaceous fossils. A similar behaviour can be expected for phosphate.

Let us suppose that the very positive δ's are the closest to the original values and that the deposition of the phosphate always occurred under conditions of isotopic equilibrium. Assuming that the temperature range of the Jurassic ocean was not very different from that of the modern oceans, say 20 ± 10° C, one should conclude that the oxygen isotopic composition of ocean water was much more positive at that time than it is now. The presumable difference is of the order of magnitude of 5–9 per mil. Since this difference is extremely large, it is rather difficult to accept these values, without even questioning their validity. The possibility of a variation of the oxygen isotopic composition of the ocean water with time was discussed by Silverman[6], who considered that the continuous deposition (either organic or inorganic) of carbonates, phosphates, silicates, sulphates, etc., would progressively deplete sea water of oxygen-18 because of the fractionation effect produced during the deposition of these chemical compounds. The most recent arguments put forward in this field were by Craig[7], who pointed out the difficulty of making any kind of detailed balance for the oxygen isotopic composition of sea water during the past. The principal processes involved in a possible evolution of the oxygen isotopic composition of sea water[7,8] are weathering, erosional and sedimentation processes and the possible addition of juvenile water. No evaluation can be made of the contribution of juvenile water and, consequently, no conclusions can be drawn even if it seems likely that there has been a progressive depletion in oxygen-18 in sea water.

In general, the results obtained from Upper Cretaceous fossils seem to agree with such a hypothesis. Following the same considerations as for Jurassic samples, the difference in the oxygen isotopic composition between Upper Cretaceous water and modern water is reduced to about 1–5 per mil. However, a variation of several per mil in less than 100 million years seems to be quite large. In order to make a first approximation to the possible effect on the isotopic composition of ocean water of only the sedimentation processes, let us assume the total mass of ocean water to be $1{\cdot}37 \times 10^{24}$ g and the value of 0·2 cm/1,000 years to be the most probable one for the rate of accumulation of *Globigerina* ooze sediments. Assuming this as an average rate of sedimentation for the whole area covered by oceans, such a sedimentation, acting over a 100 million year period, would produce a variation in the average oxygen isotopic composition of sea water of about +2·5 per mil. This assumes an average value of 1·03 for the fractionation factor of oxygen (α) for the precipitation (either chemical or biological) of the different chemical compounds in the sediments and does not take into account the effect of the other variables which can greatly increase or reduce the isotopic effect.

If one tries to calculate t and δ_w from equation (1) and the Epstein equation it can easily be seen that the system cannot be solved with the values obtained from the measurements of fossils, either belemnites or other organisms.

Plotting δ_{18O} (PO_4^{3-}) against δ_{18O} (CO_3^{2-}), independently of the oxygen isotopic composition of the ocean water, a distribution similar to that in Fig. 2 should be obtained. In Fig. 4 it can be seen that this does not happen. In the case of samples 9 and 12 (the only two Palaeozoic fossils containing measurable amounts of both carbonate and phosphate) the values, which are very different from all the other results obtained, again lead to the conclusion that an extensive isotopic exchange occurred for both

carbonate and phosphate. It is extremely difficult to draw any definite conclusions in the case of the other fossils. It can be said, generally speaking, that belemnites show more positive δ values, both for carbonate and for phosphate. Further measurements will be required to decide whether this is the result of better preservation of the original oxygen isotopic composition or of other causes; it must be pointed out, however, that spot measurements of the oxygen isotopic composition of carbonate carried out on some Jurassic belemnites between the apical canal and the external surface showed that, in the specimens measured, some isotopic exchange occurred between carbonate and ground water. The results obtained from sample No. 23 are given in Fig. 5; similar results were obtained from other belemnites. The external portion of the rostrum and the portion near the apical canal show δ values which evidently arise from an isotopic exchange with ground water. Clayton and Stevens[9] obtained results of the same type from New Zealand belemnites.

Further measurements on phosphatic fossils of different ages are now in progress.

I thank Prof. E. Tongiorgi, Prof. H. Craig and Dr. R. Gonfiantini for helpful discussions, Mr. S. Nuti for his valuable assistance and the following persons for kindly supplying samples: Dr. A. J. Rowell, University of Nottingham; Dr. D. G. Montagne, director of the Maastricht Museum; Dr. P. Fritz, Technische Hochschule, Stuttgart; Dr. W. Medwenitsch, University of Wien; Drs. J. Sornay, R. Letolle and J. C. Fontes, University of Paris; Drs. H. Dighton Thomas, H. A. Toombs and H. W. Ball, British Museum (Natural History), London; Dr. D. H. DETERMINATION OF THE ABUNDANCE OF CARBON AND NITROGEN ISOTOPES IN DUTCH COALS AND NATURAL GAS

By C. BOKHOVEN and H. J. THEEUWEN
Central Laboratory, Dutch State Mines, Geleen, The Netherlands

It has been pointed out by Patijn[1] that the presence of large deposits of natural gas in the north-east of The Netherlands may be the result of a recoalification process in the subsurface coal seams of great parts of The Netherlands. Although this theory would seem to give a reasonable explanation of the formation of methane, it does not account for the occurrence of varying and relatively large amounts of nitrogen in Dutch natural gas. Consequently, it has been assumed[2] that the nitrogen in this gas is of atmospheric origin.

In this connexion, it seemed of interest to determine the abundance of the carbon and nitrogen isotopes in coal samples of different seams as well as in samples of natural gas and mine gas.

The determination of the isotope ratios was carried out using an '*MS3*' mass spectrometer, manufactured by Associated Electrical Industries, Ltd., of Manchester, incorporating the modifications outlined by Shackleton[3]. This modified instrument is capable of measuring differences as small as 0·001 per cent in the isotope abundance of carbon-13 and nitrogen-15 in carbon dioxide and nitrogen samples, respectively.

For the measurement of the carbon isotope ratios, a primary and a secondary standard were used.

Diphenantryl ($C_{28}H_{18}$) was taken as the primary standard. The abundance of carbon-13 was determined by measuring the ratio of the peak heights at *m/e* 354 and 355. (This measurement was carried out on an A.E.I. type *MS* 9 mass spectrometer with high resolving power.) The resulting value, which was corrected for a small contribution of the dihydro- and tetrahydro-compounds, amounted to 1·079 ± 0·001 atom per cent. After combustion to carbon dioxide no difference could be detected between the values for the carbon dioxide contents of the primary and secondary standards; the latter standard was used for comparison with the carbon dioxide obtained by combustion of the coal and gas samples.

Atmospheric nitrogen was applied as a standard for the measurement of the nitrogen isotope abundance. This standard was based on a sample of pure nitrogen from an air separation plant and a sample of air which had been freed from oxygen by absorption in an ammoniacal solution of cuprous chloride. The two samples showed the same abundance of nitrogen-15 isotope.

The combustion of the coal samples, which had been dried at 100° C, was carried out in a stream of pure dry oxygen in an electrically heated tube. The resulting carbon dioxide was trapped on silica at −78° C. After the oxygen had been pumped off at −196° C, the carbon dioxide was desorbed in the sample bottle to be analysed in the mass spectrometer. In addition to this procedure, coal samples were burnt in a combustion calorimeter at an oxygen pressure of 20 atm. In this case also the oxygen was removed from the carbon dioxide by pumping at −196° C.

A definite amount of natural gas (300 ml.) was burnt by passing it in a closed circuit over copper oxide at a temperature of 850° C. After removal of the carbon dioxide the sample could also be used for the determination of the nitrogen isotope ratio.

Finally, the organic nitrogen of coal was converted to elementary nitrogen by Kjeldahl digestion and subsequent oxidation of ammonium chloride with sodium hypobromite.

The characteristic properties of the coal samples and the composition of the gas samples used in this investigation are summarized in Tables 1 and 2. Table 3 lists the isotope ratios for the different coal samples as well as for the gas samples.

From the results it appears that the variations in the isotopic ratio for coal samples with a wide stratigraphical range and a great difference in degree of coalification are only slight. In view of these variations, the mine gas samples should be considered as strongly depleted in carbon-13. The natural gas from the Slochteren bore, however, seems to be only slightly depleted in carbon-13.

It is well known[4] that in irreversible decomposition reactions the ^{12}C—^{12}C bond is slightly more liable to rupture than the corresponding ^{12}C—^{13}C bond. This isotope effect is dependent on temperature, in the sense that high temperature processes show little, if any, isotope discrimination.

The carbon isotope effect, which has been established for a number of decarboxylation reactions[5], may also be expected to occur in the demethanation process. Since the reaction with the heavy isotope lags behind that with the lighter isotope, and the amount of methane evolved is small compared with the total amount of carbon available (the amount of methane liberated in coalification from 34–31·5 per cent volatile matter is 12 m³ per ton of coal[6]), it may be expected that the mine gas methane is depleted in carbon-13. This is confirmed by our results.

The dependence of the isotope fractionation on temperature is demonstrated by the slight depletion of the methane obtained in the carbonization experiment with a sample of the Emma coal seam, which was heated at a rate of 3° C/min. The gas sample, predominantly consisting of hydrogen and methane, was taken in the temperature range 400°–600° C.

The depletion found for the Slochteren gas supports the view that the Dutch natural gas originates from a recoalification of coal seams located at depths between 3,000 and 5,000 m below the sea level[1]. During the recoalification at these depths the temperature may have been higher than in the coalification of the Limburg coal seams, and this may explain, at least qualitatively, the different degrees of depletion. (The estimated temperature gradient during the Carboniferous era is 12–15 m/°C (ref. 1). The present temperature gradient in The Netherlands in formations overlying the Palaeozoic is 25–30 m/°C.)

As regards the abundance of nitrogen-15 in the nitrogen from coal, compared with that in the nitrogen present in natural gas and mine gas, it is interesting to note that the nitrogen in the gases is enriched in nitrogen-15 (Table 4). On the other hand, ammonia from coke-oven gas, which

Ammonia from coke-oven gas	0·358[3]	− 9

* Nitrogen-15 atom per cent = $\frac{100}{2R + 1}$ with $R = \frac{^{14}N\ ^{14}N}{^{14}N\ ^{15}N}$

† $\delta\ ^{15}N/^{14}N = \frac{^{15}N/^{14}N\ (\text{sample}) - ^{15}N/^{14}N\ (\text{standard})}{^{15}N/^{14}N\ (\text{standard})} \times 1{,}000.$

in contrast with pyridine must have been formed by the rupture of C—N bonds, appeared to be depleted in nitrogen-15.

As it is difficult to conceive of chemical processes for the conversion of the organic nitrogen to elementary nitrogen and as, moreover, such processes would discriminate in favour of the lighter isotope, it must be concluded that the nitrogen in the natural gas was probably not originated in the coal.

The relation with the atmospheric nitrogen must, however, be left for further consideration. The enrichment in nitrogen-15 could be conceived to result from bacteria fractionation (for example, nitrogen fixation processes) which has already been reported for sulphur[7] and carbon isotopes[8], but so far no evidence in support of this view has been found.

We thank Dr. R. J. H. Patijn, of the "Geologisch Bureau voor het Nederlandse Mijngebied" at Heerlen, for raising the problem of isotope fractionation and for supplying some of the samples used in this investigation.

A HOMINID TOE BONE FROM BED I, OLDUVAI GORGE, TANZANIA

By Dr. M. H. DAY
Department of Anatomy, The Middlesex Hospital Medical School, London, W.1
AND
Dr. J. R. NAPIER
Unit of Primatology and Human Evolution, Royal Free Hospital School of Medicine, London, W.C.1

During the excavation of site *FLK* North (*FLK N1*) at Olduvai Gorge, a hominid toe bone (Fig. 1, *a–e*) was recovered on November 16, 1961, by Mr. Joseph Mutaba, an assistant of Dr. L. S. B. Leakey.

The bone was found at Level 5, one of four superimposed occupation levels 3–3·5 ft. below the marker bed in the upper part of Bed I, and was associated with chopper tools and other implements typical of the Oldowan culture. In addition numerous broken mammalian bones were found. Despite extensive excavation no further hominid bones were found. From the site and stratigraphy, it seems that the toe bone has no direct connexion with the other hominid remains already known from the *FLK* area; the *Australopithecus* (*Zinjanthropus*) *boisei* skull and the *Homo habilis* cranial and post-cranial material from Bed I (including the foot) were recovered from much lower levels. On a purely stratigraphic basis, Hominid 16 from *FLK* II (Maiko Gully) is probably the nearest, as this skull seems to have eroded out of the clay 4–5 ft. above the marker bed; however, Maiko Gully is several hundred yards distant from *FLK* North.

The bone is the right hallucial terminal phalanx of an adult hominid, and is complete and undistorted. The reason for ascribing this bone to the right side is given below. In shape the bone is short, broad, and flattened from above downwards. It presents an oval base, which bears a divided facet for articulation with the head of the proximal phalanx, and lateral tubercles for the attachment of the collateral ligaments of the interphalangeal joint. The base is marked underneath with an arcuate tubercle for the attachment of the flexor hallucis longus, while the head bears a prominent tuberositas unguicularis. From above, the bone displays a broad head and a broad base separated by lateral asymmetrically arranged mid-shaft indentations. These are so arranged that the head of the bone is tilted to the right. Finally, and perhaps, from a functional point of view, of most significance, when viewed from the front, the bone is twisted in its length, a condition known as axial torsion (Fig. 1*e*).

The toe bone has been compared with samples drawn from populations of modern man (including Bushman), gorilla and chimpanzee; comparison has also been made with casts of the Neanderthal hallucial terminal phalanges from Kiik-Koba and Skuhl. Anatomically, the Olduvai terminal phalanx shows greatest resemblance to that of modern man, but its morphology is not precisely matched by any of the hominoid bones or casts which we have examined.

Metrically the most striking feature of the bone is its exceptionally high length/breadth index (Fig. 2); it is broader than it is long, a condition not found in modern man but shared with the Kiik-Koba bone alone.

It has been shown that valgus deviation of the terminal phalanx of the great toe is invariably present in modern human adults, as well as in children and stillborn foetuses drawn from several races[1,2]. This deviation, present even in the unshod, has been linked with man's unique gait[2]. Measurements made in a series of modern human and pongid bones confirm the previous findings and suggest that this deviation is more often absent or has a varus inclination in pronograde quadrupedal primates (Fig. 3).

The Olduvai toe bone has a deviation of 2° to the right (determined by a triangulation method and confirmed by the tilt of the head and the asymmetry of the mid-shaft waisting); this figure is outside the modern human range in our series and also in that of Barnett[2]. In order to decide for an unknown bone whether the direction of this deviation is varus or valgus, it is necessary to establish to which side the bone belongs. Wilkinson[3] states that in modern man the tubercle for the insertion of flexor hallucis longus extends more distally on the fibular side than on the tibial side of the terminal phalanx, and may even reach the unguicular tuberosity. On these grounds the Olduvai toe bone can be referred to the right side and the deviation thus confirmed as being valgus in direction.

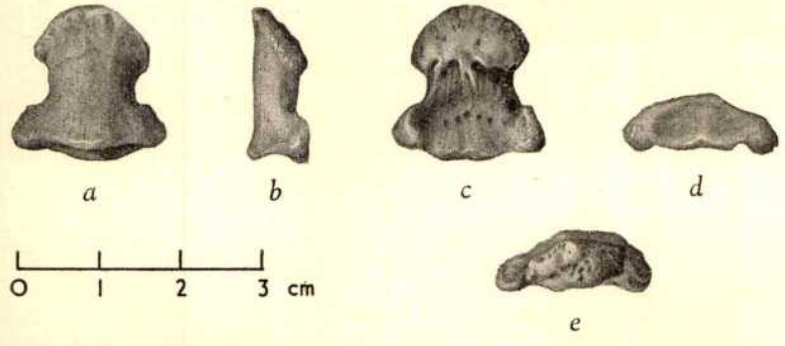

Fig. 1. The terminal phalanx from Olduvai Gorge (Hominid 10), drawn by Mrs. A. Besterman.

A further feature of the Olduvai ungual phalanx to which particular attention must be directed is its degree of axial torsion. Modern human terminal phalanges possess a range of lateral torsion which does not seem to have been described previously. An assessment of this characteristic and its possible phylogenetic and functional significance will be published elsewhere by one of us (M. H. D.); meanwhile the normal ranges of variation for this feature are given for modern man (including Bushman), gorilla, chimpanzee, and for two single examples of Neanderthal man (Fig. 4). The Olduvai and Neanderthal toe bones lie squarely within the modern human range for this feature, while the modern pongids

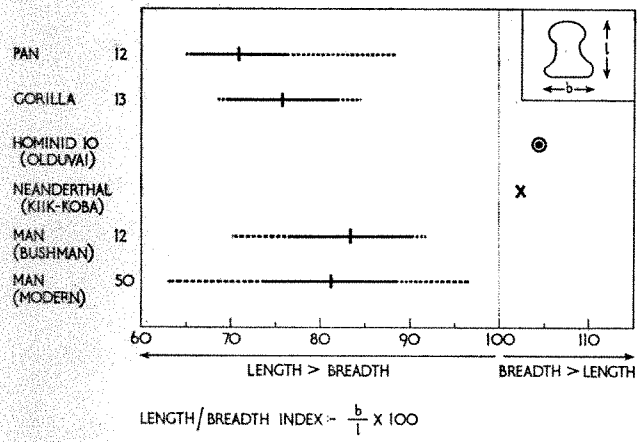

Fig. 2. The length/breadth index of the Olduvai terminal phalanx compared with that of modern man, Neanderthal man, modern gorilla and modern chimpanzee (mean, total and *S.D.* ranges).

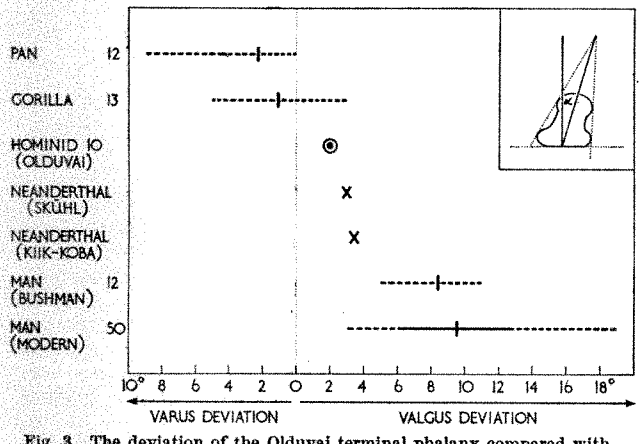

Fig. 3. The deviation of the Olduvai terminal phalanx compared with that of modern man, Neanderthal man, modern chimpanzee and modern gorilla (mean, total and *S.D.* ranges).

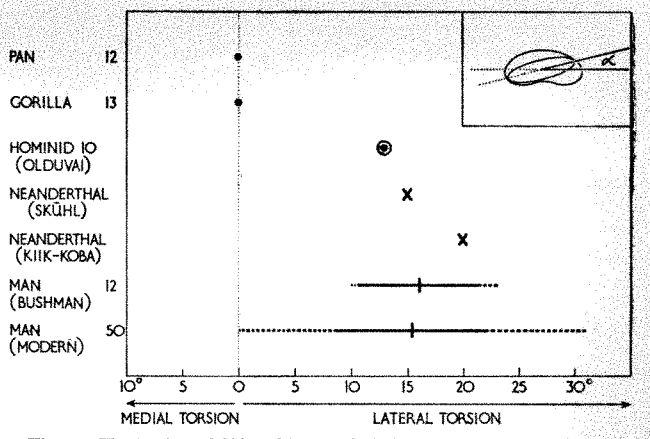

Fig. 4. The torsion of Olduvai terminal phalanx compared with that of modern man, Neanderthal man, modern chimpanzee and modern gorilla (mean, total and *S.D.* ranges).

examined show no lateral torsion at all. With regard to the magnitude of axial torsion of the terminal phalanx of the great toe there is, therefore, a clear distinction between those forms which have a pronograde quadrupedal gait and those with a plantigrade bipedal gait.

The implications of the combined presence of valgus deviation and lateral torsion are of the greatest functional significance. With respect to valgus deviation of the great toe it has been said: "Unfortunately the distal phalanx of the hallux is seldom recovered in fossil form, but the discovery of a valgus deviation in the bone of an extinct creature would provide evidence for a human type of gait"[2]. The discovery of lateral torsion, another specific feature associated with a modern type of gait, allied with valgus deviation in the same fossil bone strongly suggests, therefore, that the Olduvai toe bone belonged to an upright bipedal hominid possessing a plantigrade propulsive gait.

On the basis of an isolated toe bone it is clearly not possible to allocate the fossil to a known specific taxon; no comparable bone of any other form is available from Lower or Middle Pleistocene deposits. Nevertheless it must be borne in mind that a comparable type of gait has already been ascribed to the *Homo habilis* foot recovered from a lower level in the same deposits at Olduvai Gorge[3].

This terminal phalanx from Bed I (Hominid 10) provides further evidence for an advanced form of bipedal gait in the early hominid forms which were evolving in East Africa during the Upper Villafranchian.

We thank Dr. L. S. B. Leakey for the opportunity to study and report this new material.

COMPUTER RAY TRACING OF THE OPTICAL SYSTEM OF THE SCHEMATIC EYE

By Dr. ROBERT S. LEDLEY and GEORGE C. CHENG
National Biomedical Research Foundation, Silver Spring, Maryland
AND
WILLIAM M. LUDLAM
Optometric Center of New York, New York City

The theory of the schematic eye, as originally developed by Listing and Helmholtz and improved by Gullstrand and others[1-3], has played an important part in characterizing the image-formation capabilities of the normal, the myopic, and the hyperopic eye. A large part of present knowledge concerning the human eye arises from these remarkable investigations, even though Gaussian geometric optics, in which the aberrations are entirely ignored, were used.

Within the past decade, however, the method of ray tracing by means of electronic digital computers[4-7] has revolutionized the analysis of optical systems, since it

Table 1. PARAMETERS OF THE SCHEMATIC EYES (BASED ON GULLSTRAND'S MODEL)

Parameters	Relaxed[8]	Accommodated (at 300 mm)[11]	Relaxed[8]	Accommodated (at 100 mm)[8]

Outer portion of lens	1·410	1·410	1·386	1·386
Core-lens	–	–	1·406	1·406

automatically encompasses all the aberrations that occur. Even though this technique has been extensively applied to the design of photographic lens systems, to our knowledge it has never until now been applied to the investigation of the optical system of the human eye. The purpose of this article is to describe our first results with such an approach. In particular, we present here the effects on image formation of variations in pupil size, refractive indices, and curvatures of the cornea and lens, utilizing schematic-eye values based on Gullstrand's model. (See Table 1.)

Computer Programme. A ray-tracing computer programme called *ARIS* (Automatic Retinal Image Study)[8] was formulated. The programme traces a large number of rays from an object point on the optical axis and computes for each the refraction as it passes through the surfaces of the cornea and the lens, including core surfaces, in a multi-layered lens. In addition, the programme can automatically adjust the object distance for retinal image formation, and can vary the curvatures and indices of refraction of the optical elements of the eye for iterative ray-tracing computations. Because *ARIS* does not involve the limitations of a Gaussian approximation, those parameters most commonly considered in optometry such as refractive power were not used, and a more suitable set of parameters was chosen. Fig. 1 shows the parameters actually used in *ARIS*.

Aperture Size Variation. Fig. 2*a* shows the effects of variation in aperture diameter (which is proportional to pupil size) on the location of the least-confusion disk with

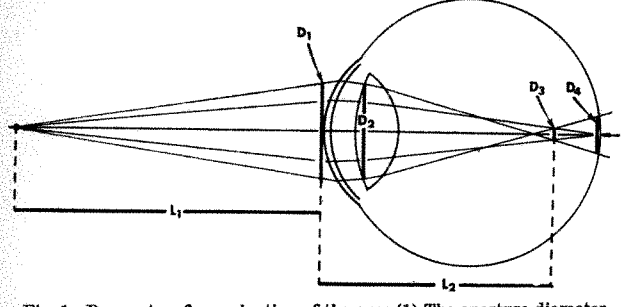

Fig. 1. Parameters for evaluation of the eye: (1) The aperture diameter at the anterior pole (D_1). (2) The pupil diameter (D_4). (Note that the pupil diameter is about 89 per cent of the aperture diameter at the anterior pole on a range from 1 mm to 8 mm.) (3) The least-confusion disk diameter (D_2). (Note, for the case of myopia, that the least-confusion disk is in front of the retina; and for hyperopia, at the back of the retina.) (4) The retinal image diameter (D_4). (5) The source distance (L_1) is that between the source point and the anterior pole of the eye. (Note that if the least-confusion disk corresponding to this source point is formed on the retina, the source distance is called the focusing distance.) (6) The least-confusion disk distance (L_2) is that between the least confusion disk and the anterior pole.

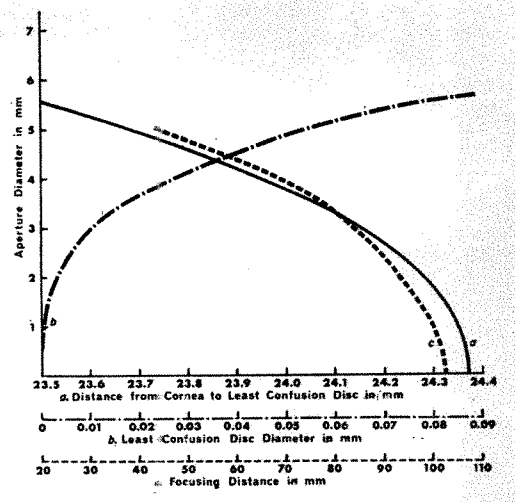

Fig. 2. Effect of pupil aperture diameter on (*a*) distance from cornea to least-confusion disk, (*b*) diameter of least-confusion disk, and (*c*) focusing distance. Curves (*a*) and (*b*) are based on the schematic eye parameters of column *C* of Table 1; curve (*c*) is based on column *D* of Table 1.

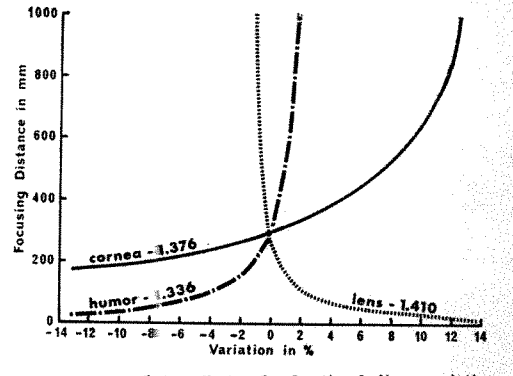

Fig. 3. Comparison of the effects of refraction-indices variation. The curves are based on schematic eye parameters of column *B* in Table 1.

respect to the cornea. The curves indicate that increasing the pupil size moves the least-confusion disk towards the cornea (that is, away from the retina in myopic eyes); this result is consistent with the phenomenon of "night myopia" for emmetropes and myopes, and indicates the expected improved image quality for hyperopes. Fig. 2*b* shows the results of varying aperture size on the diameter of the least-confusion disk. The figure demonstrates quantitatively how the image quality deteriorates with increasing pupil size. Fig. 2*c* shows the effect of aperture size on focusing distance. Here the focusing distance is measured from the front of the cornea to the point object which has its least-confusion disk on the surface of the retina. This figure illustrates that improving the ambient light, and thus reducing the pupil size, will improve vision at greater object distances. For example, well-lighted traffic intersections will enable direction signs to be read more easily from farther away for the same illumination on the sign.

Refractive Index Variation. Fig. 3 shows the effect of variation of the indices of refraction on the focusing distance. In this figure many results are combined in a single diagram. The point of intersection of all the curves represents the nominal indices and optical-element curvatures given in Table 1. Each curve shows the effect on the focusing distance of varying only the index associated with it, all other indices and curvatures remaining at the values given in Table 1. Note that as the index of both the vitreous and aqueous humour increases and approaches that of the lens, the curve rises asymptotically to a value beyond which a real focus in space will not occur. Reducing the index of the lens toward the value of the humour has a similar effect. These results are consistent with the

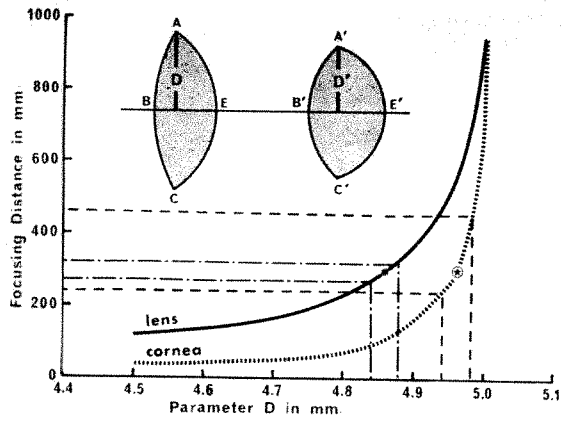

Fig. 4. Comparison of effect of curvature variation. Parameter D is the distance from centre to circumference of the lens or corneal section varied. The insert shows the manner in which D affects the curvature of the lens surfaces. The arc lengths ABC and AEC are held constant (at 10·47 mm and 8·83 mm respectively) as the distance D is varied. (For example, as D is reduced from 5·00 mm to 4·51 mm, the radius of curvature ABC is reduced from 10·00 mm to 5·62 mm and that of AEC is reduced from −6·00 mm to −4·77 mm.) Similarly, the curvatures (both positive) of the two surfaces of the cornea are varied by changing the centre-to-circumference distance. The solid curve shows the effect on the focusing distance of varying D for the lens with the curvatures for the corneal surfaces held at their original nominal values; the dotted curve shows the effect on the focusing distance of varying D for the cornea while the curvatures of the lens surfaces are held constant at their original nominal values (represented by the dark circle on the solid curve). Note how much greater is the effect of the same change in D applied to the cornea than applied to the lens. This is because the principal refraction takes place at the cornea-to-air interface. The curves are based on the schematic eye parameters of column B of Table 1.

claim that an increase in the index of refraction of the lens in diabetics can result in transient myopia[9].

Curvature Variation. Fig. 4 gives the effect of changes in the curvatures of the lens and cornea on the focusing distance. The circle on the lens curve and the star on the cornea curve are the "normal" values given in Table 1. The changes of curvatures are represented by varying a chord length D while the arc lengths subtended by the chord are held constant for the lens and for the cornea (see insert in Fig. 4)—although of course the lens and cornea do not change curvature in this manner. The curve for the lens gives the effect on the focusing distance of the change of curvature of the lens surfaces for the nominal corneal curvatures. The curve for the cornea gives the effect on the focusing distance of the change in curvature of the cornea surfaces for the nominal lens curvatures. Notice that the same change ΔD in chord length will have about four times the effect for the cornea as for the lens on the focusing distance.

Limitations and Conclusions. The limitations of our initial investigations using the programme *ARIS* (but *not* the limitations of the *ARIS* programme itself) are in the approximation (inherent in the Gullstrand schematic eye) of a centred system, spherical optical surfaces, and too few layers of the lens. In future investigations, however, it is intended to take these effects and many more into account, and also to include consideration of entire image formations and physical-optics interactions in the image formation[10]. The computer ray-tracing method presents a powerful new tool for investigating in detail the many effects that must be taken into account if a thorough understanding is to be obtained of the image-forming capabilities of the eye.

SEQUENCE OF LINKAGE BETWEEN THE PROSTHETIC GROUPS AND THE POLYPEPTIDE CHAINS OF HAEMOGLOBIN

By DR. K. H. WINTERHALTER

Institute of Histopathology, University of Zurich

ALTHOUGH the biosynthesis of tetrapyrroles and the synthetic pathways of polypeptides have been extensively investigated, little is known about the site and sequence of combination between haem and the polypeptide chains of haemoglobin. Haemoglobin A has a molecular weight of 64,000 and consists of four polypeptide chains, namely two alpha and two beta chains, each of which carries a haem molecule. In a recent publication, it has been shown that globin has a molecular weight of 32,000 and the composition alpha-beta[1]. Addition of more than 4 moles of haemin in a solution containing cyanide to two moles of globin resulted in a protein that was indistinguishable by a variety of criteria from cyanmethaemoglobin A and that had a sedimentation coefficient of 4·1 and 4·4, depending on protein concentration, thus indicating the formation of a haemoglobin molecule containing four polypeptide chains[1]. It was therefore concluded that the combination with haem favoured the association between the polypeptide subunits.

The overall reaction is given by formula 1*.

$$\underset{\text{Globin}}{2\,\alpha\beta} \xrightarrow{4\ \text{haem}} \underset{\text{Haemoglobin A}}{\alpha^h\alpha^h\beta^h\beta^h} \qquad (1)$$

On theoretical grounds, it could, therefore, be postulated that the combination between haemin and globin involves the following steps (formula 2)*

$$\underset{\text{Globin}}{2\,\alpha\beta} \xrightarrow{+1\,h} \begin{matrix}\alpha\beta^h\\ \alpha^h\alpha\beta\beta\\ \alpha\alpha\beta^h\beta\end{matrix} \xrightarrow{+1\,h} \begin{matrix}\alpha^h\alpha\beta\,\beta\\ \alpha^h\alpha\beta^h\beta\\ \alpha\alpha\beta^h\beta^h\end{matrix} \xrightarrow{+1\,h} \begin{matrix}\alpha^h\alpha^h\beta\beta\\ \alpha^h\alpha\beta^h\beta^h\\ \alpha^h\alpha\beta^h\beta^h\end{matrix} \xrightarrow{+1\,h} \underset{\text{Haemoglobin A}}{\alpha^h\alpha^h\beta^h\beta^h} \qquad (2)$$

Haemoglobin in solution is in rapid association–dissociation equilibrium according to the formula*

$$\alpha^h\alpha^h\beta^h\beta^h \underset{1}{\rightleftharpoons} 2\,\alpha^h\beta^h \underset{1}{\rightleftharpoons} 2\,\alpha^h + 2\,\beta^h \qquad (3)$$

The formula $\alpha^h\beta^h$ on addition of $2h$ to $2\alpha\beta$, therefore, appears unlikely, as this would immediately lead to the association, resulting in the formation of haemoglobin. This, in turn, would exclude the formation of compounds having three haems per four polypeptide chains. On the basis of formula 2, three classes of intermediary compounds in the combination between globin and haemin were to be expected, having the ratios haemin : polypeptides 1 : 4, 2 : 4 and 3 : 4, respectively. All possible formulae of these

* The symbol h denotes one molecule of haemin.

three intermediary compounds are listed in formula 2. A search for these postulated compounds was, therefore, started. The results reported here demonstrate the existence of such compounds and give some of their characteristics.

All chemicals used in the experiments were reagent grade. Globin was prepared as previously described[1]. Haemin was prepared according to the method of Labbe and Nishida[2]. Haemin solutions were obtained by dissolving 2–3 mg of haemin in 0·2 ml. of 0·1 N sodium hydroxide and subsequent dilution to the desired concentration, with 0·01 M sodium hydrogen phosphate containing 100 mg potassium cyanide/l., after the *p*H of this buffer had been brought to 7·5 with concentrated phosphoric acid.

Intermediary compounds were obtained by mixing 2 moles of globin with less than four times equimolar amounts of haemin. For the isolation of intermediary compound II (I.C. II) 2·0 moles of haemin were added per 64 mg of globin.

The intermediary compound II was isolated on a column 50 cm long and 9 mm in diameter, packed with '*CM* Sephadex *C* 50' (Pharmacia). The column was equilibrated with 0·01 M sodium hydrogen phosphate which contained 100 mg potassium cyanide/l. The *p*H of this buffer had been brought to 6·8 by addition of concentrated phosphoric acid. Haemin–globin mixtures containing about 100 mg protein in about 5 ml. were dialysed overnight against the same buffer and then applied to the column. Elution was carried out by a non-linear gradient, obtained by the addition of 0·02 M sodium hydrogen phosphate containing 100 mg potassium cyanide/l. to a 250 ml. constant-volume mixing chamber containing the buffer of *p*H 6·8.

Estimation of molecular weight was carried out on a column 150 cm long and 11 mm in diameter, packed with 'Sephadex *G* 100' bead form and equilibrated with 0·1 m *tris* hydrochloric acid buffer *p*H 7·2 containing 100 mg potassium cyanide/l. Bovine plasma albumin grade *A*, bovine pancreas ribonuclease grade *A* (both from Calbiochem), ovalbumin five times crystallized (Serva Entwicklungslabor Heidelberg, Germany), blue dextran (Pharmacia, Uppsala), HPO_4^{2-} ions and glycine served as markers. For the determination of the elution volume the first point of inflexion of the optical density curve at 280 m was taken. This closely approximated half the maximum height of the curve. The protein samples were applied in 0·2 ml. of the buffer used for equilibration. After the sample had sunk into the 'Sephadex' gel, the walls of the glass column above were rinsed three times with 0·2 ml. of buffer and the sample afterwards eluted with the same buffer. Starch gel electrophoresis was performed in a cold room at 4° C with a discontinuous buffer system at *p*H 8·6 using 0·076 M *tris* (2-amino-2-hydroxymethylpropane-1 : 3 diol) and 0·005 M citric acid for the gel and 0·30 M boric acid – 0·06 M sodium hydroxide for the buffer vessels[3]. Spectra were obtained with a model *DK* 2 Beckman automatic recording spectrophotometer.

Globin A prepared by our methods always shows on starch gel electrophoresis a main zone comprising more than 95 per cent of the protein and a minor zone with slightly greater anodic mobility. In contrast to the main band, this zone gives a slight blue colour reaction with benzidine stain, thus indicating the presence of haem.

Addition of 4 μmoles haemin to 2 μmoles globin (mol. wt. 32,000) results in the formation of a protein which behaves electrophoretically like haemoglobin A (Fig. 1). Addition of less than 4 μmoles of haemin to 2 μmoles of globin results in the formation of three electrophoretically distinct bands which, at *p*H 8·6, show an anodic mobility between globin A and haemoglobin A (Fig. 1). The addition of small amounts of haemin (approximately 1 μmole per 2 μmole globin) leads to the intensification of the slightly more acidic band (Fig. 1, iii) (intermediary compound I). Addition of 2 μmoles of haemin leads to the formation of another still more acidic protein in much larger quantities (intermediary compound II), with a corresponding decrease in density of the globin and intermediary compound I bands. At this point, a third weak band with still greater anodic mobility (intermediary compound III) frequently appears and often a band with the mobility of haemoglobin A as well. On further addition of haemin, the globin band, and often also the band of intermediary compound I, disappear. The increase in density of the haemoglobin A band is accompanied by the successive disappearance of the bands of intermediary compounds II and III, until finally, by adding more haem, all the protein has been converted into haemoglobin A (Fig. 1). Intermediary compound II appeared as the quantitatively most important band and its isolation was attempted by chromatography on '*CM* Sephadex' (Fig. 2). Fig. 3 shows the starch gel analysis of pooled fractions which had been concentrated afterwards with concurrent dialysis*. The proteins in each of the sections obtained by pooling a number of chromatographic fractions could be converted into haemoglobin A by sufficient addition of haemin (Fig. 3).

The section containing only intermediary compound II was further investigated. Spectral analysis revealed that the compound had an ultra-violet absorption spectrum which closely resembled that of cyanmethaemoglobin[1] (Fig. 4). The spectrum in the range of visible light showed a marked quantitative difference although its shape was very similar to cyanmethaemoglobin (Fig. 4), and the positions of the absorption maxima and minima are identical (Fig. 4). Thus absorbance ratios of the protein maximum at 274 mμ and the maxima and minima in the range of visible light showed a marked difference.

The results of gel filtration on 'Sephadex *G*100' are summarized in Fig. 4. In the range of protein concentra-

tions used there was only very little concentration dependence of the elution volume for haemoglobin and none for globin. By comparison with the elution volumes of the marker proteins, a molecular weight of haemoglobin of 46,000 and one of 28,000 for globin has been determined. The elution volume of I.C.II and that for haemoglobin were identical. While the haemoglobin peak was almost symmetric the I.C.II peak showed some trailing.

By adding increasing but small amounts of haemin to a globin solution, the existence of three intermediary compounds—postulated on theoretical grounds—has been demonstrated. Quantitatively, the formation of I.C.II and haemoglobin is favoured. This is in agreement with the results from equilibrium studies between methaemoglobin and another haem-binding apoprotein (apomyoglobin). From their data[5] the authors concluded that the fixation of the first haem enhanced the affinity for the second. The fourth and last haem was captured more readily than any of the other three. The change of quantitative distribution between the intermediary compounds on addition of small amounts of haem further supports that concept.

From the results of gel filtration experiments it can be concluded that the I.C.II molecule must consist of four polypeptide chains, and that in size and shape it must closely resemble haemoglobin. Since I.C.II can be completely converted into haemoglobin by mere addition of haem, it must contain two alpha and two beta chains. The molecular weight of 46,000 obtained for haemoglobin —due to its subunit structure in rapid association–dissociation equilibrium—is in agreement with the results obtained by others[6]. The increased trailing observed in the elution pattern of I.C.II, however, is in keeping with the idea that dissociation into two subunits occurs more

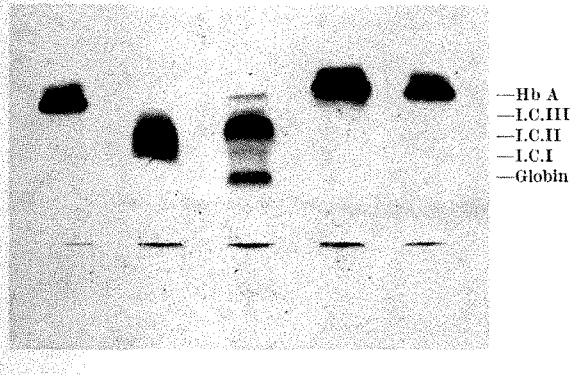

Fig. 3. Starch-gel electrophoresis conditions as in Fig. 1. i, Hb A marker; ii, isolated I.C.II; iii, globin A + 2 moles haemin/2 moles globin; iv, I.C.II + excess haemin; v, Hb A marker.

readily in I.C.II than in haemoglobin. The concept that I.C.II must have a molecular arrangement similar to that of haemoglobin is further supported by the observation that the maxima and minima of optical density have the same position, and the differences are merely quantitative ones.

The electrophoretic mobility of the band designated I.C.II is in keeping with the idea that it contains half the prosthetic group found in haemoglobin. The fact that addition of half the amount of haem needed for primary saturation of all specific binding sites leads to the formation of I.C.II (Fig. 2) supports the same idea. From the data presented in this paper we cannot decide, however, which of the three formulae postulated for I.C.II applies (formula 2). Experiments to solve this question are in progress.

Data presented in a recent publication[7] led to the conclusion that the amino-acid sequence alone was sufficient to determine the conformation of apomyoglobin in solution. Addition of haem led to a specific conformational change (significant gain of helix). From the overall formula $2\,\alpha\beta + 4\,h \longrightarrow \alpha^h\alpha^h\beta^h\beta^h$ it is obvious that addition of haem to apohaemoglobin leads to a considerable configurational change. The observation that I.C.II—in contrast to globin—consists of four polypeptide chains with an arrangement closely resembling that in haemoglobin implies that an important part of this rearrangement had taken place when the second haem is fixed.

I thank Prof. F. Leuthardt, who has kindly permitted this work to be carried out in his laboratory, and Mrs. V. Pünter and Miss R. Hess for technical assistance.

T SYSTEM CONNEXIONS WITH THE SARCOLEMMA AND SARCOPLASMIC RETICULUM

By DR. S. M. WALKER and G. R. SCHRODT
Departments of Physiology and Pathology, University of Louisville School of Medicine, Louisville, Kentucky

THE interfibrillar spaces of muscle fibres contain two membranous systems, the *T* system and the sarcoplasmic reticulum. Practically all the *T* system is oriented transversely between the fibrils. The sarcoplasmic reticulum can be looked on as longitudinally oriented between the *T* system. The terminal segments of the sarcoplasmic reticulum are, however, in close apposition to the *T* system. The space between the sarcoplasmic reticulum and the *T* system at the sites of apposition is remarkably constant and this space contains electron-opaque material which has been variously described. Recent investigations[1–3] have shown that the membranes of the *T* system are continuous with the sarcolemma at the level of the *Z* band in fish and frog skeletal muscle fibres. Similar continuity of the *T* system membranes and sarcolemma in muscle fibres of other vertebrates might also exist[1–3]. Nevertheless, it seems desirable to make observations within the group of vertebrates (reptiles, birds, and mammals) with the *T* system located at the junctions of the *A* and *I* bands.

In the interior of vertebrate muscle fibres the *T* system (*T*) is closely associated with the terminal segments of the sarcoplasmic reticulum (*R*) on either side of it. The central *T* element and the lateral *R* elements have been called a triad[4]. Numerous investigations have called attention to the constancy of the space between *T* and *R*. Lines of density alternating with less dense areas in the space between *T* and *R* have been reported[5] for bat cricothyroid muscle fibres. It has been suggested[6] that structures crossing the space between *T* and *R* are membrane-like in rat gastrocnemius muscle fibres. On the other hand, it has been suggested[7] that the apposed membranes of *T* and *R* might be fused to form tight junctions like those formed by the apposed plasma membranes of various cells[8–10]. However, it was pointed out[7] that fusion of apposed membranes of *T* and *R* has not been observed clearly. These differences in electron-microscope observations[6,7] emphasize the need for further investigations of structures at the site of the apposed membranes of *T* and *R*. The need for these investigations is enhanced by the efforts at present in progress to determine the relationship of *T* and *R* to transmission of excitation from the sarcolemma to the interior of the fibre. In the work reported here an attempt is made to show triple-layered apposed membranes of *T* and *R* and to describe the connexions between these membranes.

For investigations concerned primarily with connexions between the sarcolemma and *T* we used glutaraldehyde fixation which has been shown to be highly effective for such investigations[1–3] on fish and frog muscle fibres. Small bundles of rat gastrocnemius muscle fibres, removed from animals anaesthetized with 'Nembutal', were tied to 'Plexiglas' stays and fixed in glutaraldehyde by the method of Sabatini *et al.*[11] slightly modified. The fibres were post-fixed with osmic acid by the Palade method as modified by Caulfield[12]. The tissues were dehydrated for 10 min in 50 per cent alcohol and then placed overnight in 70 parts absolute alcohol and 30 parts saturated aqueous solution of uranyl acetate. After completion of dehydration with 95 and 100 per cent alcohol, the fibres were embedded in 'Maraglas'. Sections of the tissues were made with a Porter-Blum microtome and stained with lead hydroxide solution according to the method of Lever[13]. Sections exhibiting grey interference colours and near 500 Å in thickness were examined with a Siemens 'Elmiskop I' electron microscope.

For some of the observations on apposed membranes of *T* and *R*, fibre bundles were fixed with osmic acid, embedded in methacrylate and otherwise prepared as described. However, in these cases the sections were cut somewhat thicker and showed silver interference colours.

The characteristic apposition of membranes of *T* and *R* was found in triads at the subsarcolemmal level. This structural feature of *T* and *R* membranes made identification reliable even in sections that showed only one of the two regions of apposed membranes. In rat gastrocnemius muscle fibres the tubules of the *T* system, viewed in cross-section, are usually elliptical in shape. The long axis of the ellipse is 800–1200 Å and the short axis is 200–500 Å. Assuming that the size and shape of the opening of the *T* system in the sarcolemma are similar to interfibrillar size and shape of *T*, as seen in cross-section, it should be possible to make sections 500 Å thick whose thickness would fall within the long axis of the opening and exclusive of the boundary walls on either side of the opening. Sections thus oriented would show distinct continuity of *T* with the sarcolemma.

The connexions between *T* and the sarcolemma are found near the junctions of the *A* and *I* bands in moderately stretched fibres. The connexions occur at points where the sarcolemma shows an invagination. The connexions thus formed show a continuity between the extracellular fluid and the fluid contents of *T* tubules. The electron micrograph in Fig. 1 shows the location of the *T* system (*T*) in relation to the *A*–*I* junction and the *Z* band. The invagination of the sarcolemma and its connexion with *T* are located below the star in Fig. 1. The plane of the section is about 15° oblique to the longitudinal axis of the fibre and the terminal segment of sarcoplasmic reticulum (*R*) is shown on the left side only of *T*. In this

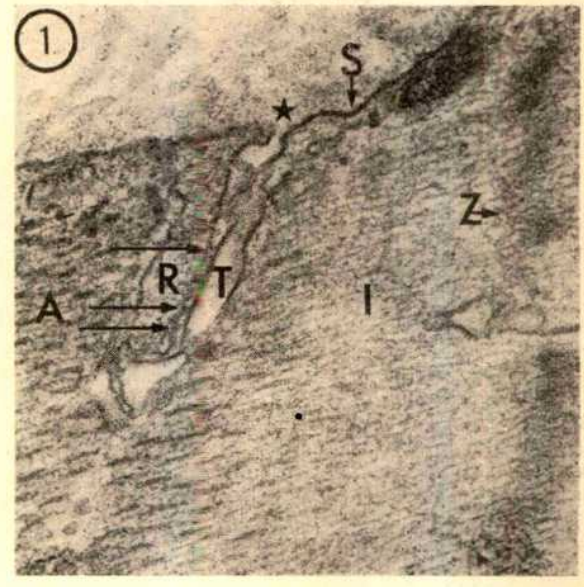

Fig. 1. Electron micrograph of rat gastrocnemius muscle fibre with the plane of the section passing about 15° oblique to the longitudinal axis of the fibre. The star indicates a point where the sarcolemma (*S*) is invaginated and connected with membranes of the transverse system (*T*). The arrows point toward dense zones across the space between apposed membranes of *T* and a terminal segment of sarcoplasmic reticulum (*R*). *A*, *A* band; *I*, *I* band; *Z*, *Z* band. Fig. 2. A high magnification of a part of Fig. 1 showing details of the connexions of the T system with S and R. The asterisks indicate points where the triple layers of S, T, and R membranes are visible. The X marks a point where the section apparently includes a tangential view of the convoluted tubular wall of T. The points of the arrows are placed at the boundaries of distal outer dense layers of triple-layered apposed membranes of T and R. M, Medial space between membranes of T and R; P, proximal outer dense layers of triple-layered membranes; D, distal outer dense layers. (× c. 260,000.)

section the width of the space between apposed membranes of T and R is not uniform throughout. In more favourable sections showing all three elements of the triad, like the one shown in Fig. 4, the space width between T and R is more constant. At a few points in Fig. 1 dense zones across the space between apposed membranes of T and R are indicated by arrows.

A part of the section in Fig. 1 is shown at higher magnification in Fig. 2. The continuity of the extracellular fluid with the fluid content of the T tubule is clearly illustrated (star). The point indicated by X apparently shows a convolution of the T tubule that causes a tangential view of the tubular wall to be included in the section. It is possible to observe the similarity of membrane structure in sarcolemma, T, and R at points of favourable section (asterisks). The membranes show two outer dense layers separated by a less dense middle layer. The total thickness of the three layered membrane of T is about 65 Å. Similar thickness is shown for the R membrane apposed with T. The sarcolemma is slightly thicker and more heavily stained. The triple layers in T and R membranes and the space between these membranes can be seen at the same level of apposition in some cases (arrows). For purposes of presentation in this investigation the space between apposed membranes of T and R and the structures within this space will be regarded as medial. The nearest and farthest outer dense layers of the apposed three layered membranes will be designated as proximal and distal, respectively. The arrows in Fig. 2 mark the boundaries of distal outer dense layers of T and R membranes at points where the triple layers can be seen in each of the apposed membranes. Now, if fusion of the type described for plasma membranes of adjoining cells[8–10] were present, the proximal outer dense layers of apposed membranes should be fused to form the intermediate layer of a five-layered structure. This would mean that the total thickness of the two membranes at the points of fusion would be somewhat less than twice 65 Å, say 120 Å. Examination of the distances between arrows in Fig. 2 shows an average distance slightly greater than 200 Å. If the location and measurements are correct, fusion of the proximal outer dense layers of the apposed membranes of T and R is impossible at the points indicated by arrows. Actually the dense zones across the space between T and R suggest intermittent connexions of the apposed membranes.

In preparations fixed initially with osmic acid, openings in the sarcolemma continuing as T tubules were never found. On the other hand, extension of T to the subsarcolemmal region of the fibre was seen several times. An example of T and R at the subsarcolemmal level, as they appear in preparations fixed with osmic acid, is shown in Fig. 3. The triple layers of the T membrane are rather well depicted in the wall of the tubule on the left side. The triple layers of the apposed membrane of R are also visible at some points on the left side of T. Here again, as in the case of Fig. 2, the apposed membranes of T and R occupy a distance (space between points of arrows) that is incompatible with the concept of fusion of these membranes. The thickness of the apposed membranes of T and R is about 75 Å in Fig. 3. This means that the combined thickness of the two apposed membranes is about 150 Å. The distance between the points of the arrows is about 225 Å. There appear to

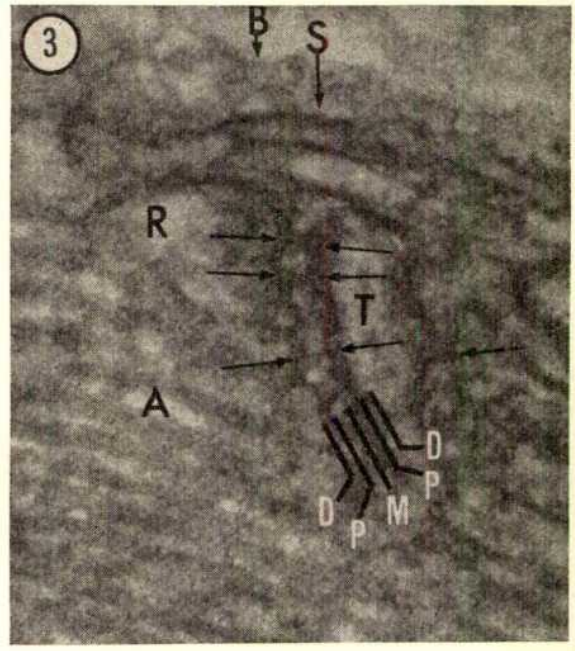

Fig. 3. Approximate longitudinal section of a fibre showing T and R near the sarcolemma (S). The points of the arrows mark the outer boundaries of apposed membranes of T and R and the connexions across the space between T and R at these points suggest the presence of triple layers typical of membrane density pattern. A, A band; B, basement membrane. Labels M, P, and D, as in Fig. 2. Osmic acid fixation. Methacrylate embedding. (× c. 280,000.)

be four rather clearly defined connexions across the space between the apposed membranes of T and R on the left side of T. At the points indicated by arrows, a membrane-like appearance of the connexions is suggested by parallel lines of density separated by a less dense space. At one point on the right side of T a membrane-like connexion between T and R is indicated by an arrow.

Fig. 4 is shown as an example of a section passing through the three elements of the triad. The section includes a relatively long longitudinal view of T. At points where the triple layers of the apposed membranes of T and R are visible at the same level there is evidence that the membranes are not fused. The arrows which mark the boundaries of distal outer dense layers of triple-layered apposed membranes are separated by about 220 Å, more or less. The thickness of the membranes is about 75 Å. This means that the distance between the proximal outer dense layers of the apposed membranes should be about 70 Å. Measurements show the average of this distance to be approximately 70 Å. Connexions across the space between T and R can be seen at four points on the left side of T, and at seven points on the right side of T. Membrane-like structures, which are comparable to those previously reported[14], are visible within R. Connexions of these membrane-like structures with the limiting membrane of R facing T (asterisks) apparently contribute to the scalloped appearance of this limiting membrane.

Contact of the T system with the sarcolemma has been shown by Revel[5] with a unique method of preparation. Fibres of bat cricothyroid muscle fixed with osmic acid in the presence of 0·01 M calcium chloride and with no subsequent staining showed rather marked electron density in the T system and the sarcolemma, in sharp contrast with other structures of the fibres which showed virtually no staining at all. Since the terminal segments of the sarcoplasmic reticulum did not show electron density, it was possible for Revel[5] to conclude that the

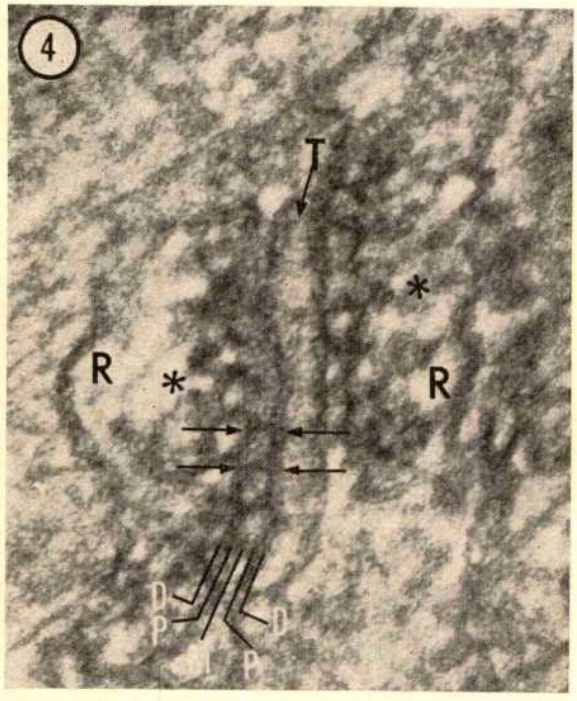

Fig. 4. Longitudinal section of a fibre showing a longitudinal section of T with R on either side of T. Four connexions across the space between T and R can be seen on the left side of T and seven on the right side. The points of the arrows mark the outer boundaries of apposed membranes of T and R. The asterisks are placed near connexions of membrane-like structures within R with the limiting membrane of R facing T. Labels M, P, and D as in Fig. 2. Osmic acid fixation. Methacrylate embedding. (× *c.* 275,000.)

structure making contact with the sarcolemma at the level of the A–I junction is indeed the T system. H. E. Huxley[15] demonstrated the presence of ferritin molecules only in the T system of frog muscle fibres soaked in Ringer's solution containing ferritin, before fixation with osmic acid. The failure to observe openings in the sarcolemma at the level of the T system led Huxley[15] to the suggestion that osmic acid fixation brings about the closure of openings of the sarcolemma into the T system. The presence of the ferritin molecules in the T system was taken as evidence that the openings are present in the living state of the fibre. At approximately the same time, Franzini-Armstrong and Porter[1] were able to demonstrate invaginations of the sarcolemma to form connexions with membranes of the T system in fish muscle fibres when they used glutaraldehyde as the fixative. The observations recorded here illustrate the superiority of glutaraldehyde over osmic acid as a fixative for demonstrating connexions between the sarcolemma and the T system.

The dense zones that traverse the spaces between apposed membranes of T and R have been designated as connexions although they have not been unequivocally established as connexions in this investigation. However, there is substantial support of the view that the dense zones are indeed connexions. In the first place, the space between the apposed membranes of T and R narrows at the level of the connexions. Secondly, the connexions appear to be membrane-like at favourable points of observation. The average distance between apposed membranes of T and R at the level of connexions (paired arrows in Figs. 3 and 4) is 73 Å. The average distance at the level of the less dense areas, interspersed between these connexions, is 92 Å. The fact that the distance at the level of connexions is shorter suggests that a holding force is exerted on the apposed membranes at this level. Such a holding force would require the dense zones to be connexions, rather than studs, between the apposed membranes of T and R. In attempts to demonstrate the presence and nature of connexions between the apposed membranes of T and R, methacrylate has a slight advantage over 'Maraglas' as an embedding material. The connexions across the space between apposed membranes are more clearly defined (Figs. 3 and 4) and a membrane-like appearance is indicated in some of these connexions. The exact nature of the connexions is not yet determined, but the results recorded here do support the view that these connexions are membrane-like. Furthermore, the results (Figs. 2, 3 and 4) show definitely that fusion of proximal outer dense layers of three-layered apposed membranes of T and R is not found with either of the two methods of preparation used in this investigation.

It is true that an anatomical tight junction, such as the one described for fused plasma membranes of adjoining cells of various types[8–10], would provide the structural requirements for the electrotonic spread of current from T to R if it were present in the apposed membranes of T and R. However, as we have suggested in the proposal of a structural model for transmission of excitation from the sarcolemma to T and R of muscle fibres[16], there is another possible structural design at the site of the apposed membranes of T and R that might form a "physiological tight junction" compatible with the electrotonic spread of current from T to R. This model is based on the observations that connexions between T and R are seen in cross-sections of the triad like that shown in Fig. 2 of a previous report[14] and in longitudinal sections as described here. These observations support the hypothesis that the less dense areas between connexions across T and R are completely surrounded by the connexions and the apposed membranes of T and R. The less dense areas may be thought of as completely sealed off from the surroundings like a sealed compartment of a honeycomb. Under these conditions, the less dense areas between T and R would be completely separated from the surrounding sarcoplasm. This structural design, if

present, might permit the effective spread of electrotonic current from T to R.

As already suggested[17], the continuity of extracellular fluid with the fluid in the T tubules indicates that the sodium concentration in these fluids is relatively high when compared with intracellular fluid. This means that a sodium concentration gradient might exist across the membranes of the T system. In the presence of an excitatory impulse the sodium gradient could play a part in current flow through the membranes of the T system.

TWO COMPONENTS OF THE CARDIAC ACTION POTENTIAL

By PROF. A. PAES DE CARVALHO
Institute of Biophysics, University of Brazil, Rio de Janeiro
PROF. B. F. HOFFMAN
Department of Pharmacology, College of Physicians and Surgeons, Columbia University, New York
AND
DR. W. B. LANGAN
Department of Physiology, Villanova University, Pennsylvania

THE notion of a cardiac action potential composed of fast and slow components (Fig. 1*A*) has often appeared in recent literature. Attempts to interpret the findings in terms of ionic movements across the cell membrane[1–6] contain evidence which suggests that (*a*) the initial fast component is related to an increase in sodium (chord) conductance and (*b*) a decrease in potassium conductance underlies the slow component. The data presented in this article add support to this concept and bring out the point that the slow component can exist and propagate even when the fast component seems to be absent.

Inspection of the transmembrane action potentials recorded from various regions of the heart suggests that, on the basis of the voltage-time relationship, they can be classified in three main groups which differ in terms of the amplitude and the maximum depolarization rate of the initial fast component of depolarization. In the rabbit atrium the three groups are represented by (*a*) cells of the pectinate muscles and crista terminalis; (*b*) perinodal cells; and (*c*) slowly conducting cells of the sinoatrial or atrioventricular nodes. Transmembrane action potentials recorded from ordinary atrial muscle fibres of the first group exhibit an initial fast phase of depolarization which extends to the peak of the action potential (Fig. 1*B*). In records obtained from perinodal cells, the initial fast depolarization finishes well before the peak of the action potential (arrow, Fig. 1*C*). The remainder of the depolarization is effected at a much slower rate. In records obtained from "true" nodal cells (sinoatrial nodal pacemaker and N region of atrioventricular node[15]) no initial fast depolarization can be detected. The transmembrane action potential arises with a very low velocity and the contour of the upstroke is smooth (Fig. 1*D*).

The cells which constitute these three groups reveal a number of differences in their pattern of response to various agents. The local application (by hydraulic ejection from a micropipette) of perfusion medium containing acetylcholine (ACh) causes the changes shown in Fig. 2. It can be seen that the initial fast component of the action potential, when present, is not depressed by ACh (Fig. 2*A* and *B*). Records of the first derivative of the transmembrane action potential show that the maximum rate of depolarization is actually increased because of the hyperpolarization caused by ACh (ref. 7.) On the other hand, the slow component of these action potentials is markedly depressed both in amplitude and duration (Fig. 2*A* and *B*). In "true" nodal cells, where a significant fast component is not present, ACh causes partial or complete abolition of electrical activity by depression of the isolated slow component (Fig. 2*C*). This action results in a failure of propagation in both the sinoatrial and atrioventricular nodes.

Local depolarization of atrial muscle fibres by the hydraulic application of potassium-rich perfusion medium from a micropipette decreases both the maximum rate of rise and the peak potential of the initial fast component of the transmembrane action potential, as would be expected[1]. The decrease in peak potential of the fast component exposes the rising phase of the slow component, which seems to be relatively insensitive to experimental modification (Fig. 3*A*). In the case of nodal cells, where

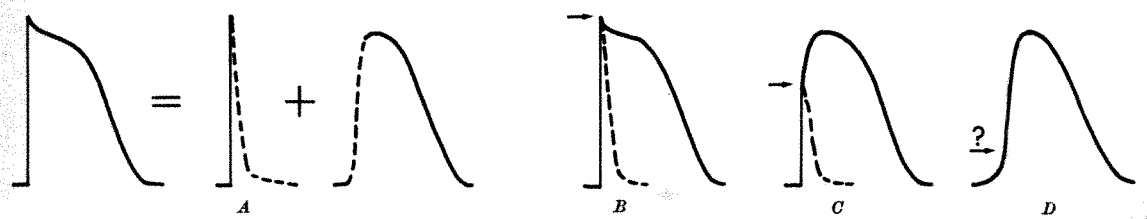

Fig. 1. *A*, Hypothetical representation of the summation of the fast and slow components of depolarization to produce the transmembrane action potential recorded from a common cardiac fibre (first group). *B*, *C*, and *D*, Schematic representation of typical transmembrane action potentials recorded from each of the three cell types described. The solid lines depict the actual voltage-time course of the record; the interrupted lines depict the assumed voltage-time course of the potential due to the isolated fast component; arrows show the peak potential attained during the fast component.

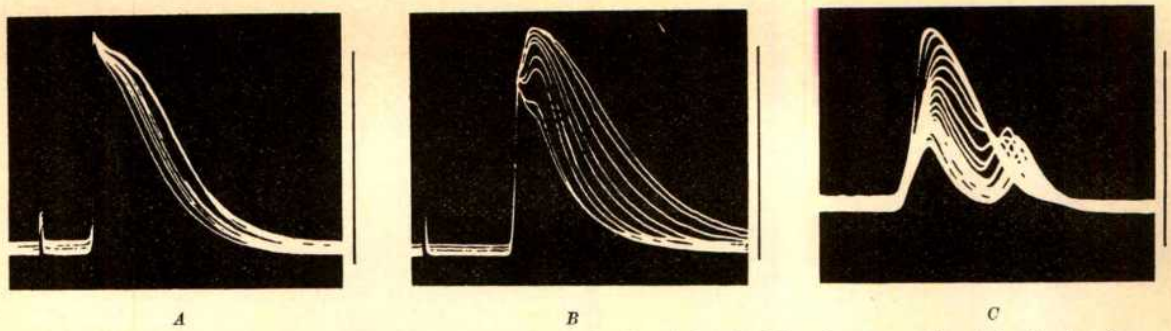

Fig. 2. Transmembrane action potentials recorded from electrically driven isolated rabbit atrium preparations during local application of ACh-containing medium. (*A*) Atrial muscle fibre, (*B*) perinodal fibre and (*C*) fibre in the *N* region of the atrioventricular node. Each record shows a number of superimposed traces recorded just before and during the local application of ACh. Note that in *A*, although there is a decrease in duration of the action potential, the upstroke and peak potential are essentially unchanged. In *B*, although the initial fast component of the upstroke is unchanged, loss of the slow component causes a decrease both in peak potential and duration. In *C*, application of ACh causes a progressive decrease in the rate of rise of the entire upstroke and also a decrease in peak potential. Also shown in *C* are potential changes by re-entrant excitation; these are not pertinent to the present discussion. Vertical lines at the right side of each block represent 100 mV.

an initial fast component is not apparent, partial depolarization by excess potassium does not significantly change the maximum rate of rise of peak potential caused by the isolated slow component (Fig. 4). Using an atropinized preparation, local depletion of sodium (by hydraulic ejection from a micropipette of perfusion medium in which 95 per cent of the sodium is replaced by choline chloride) causes the expected marked decrease in the rate of rise

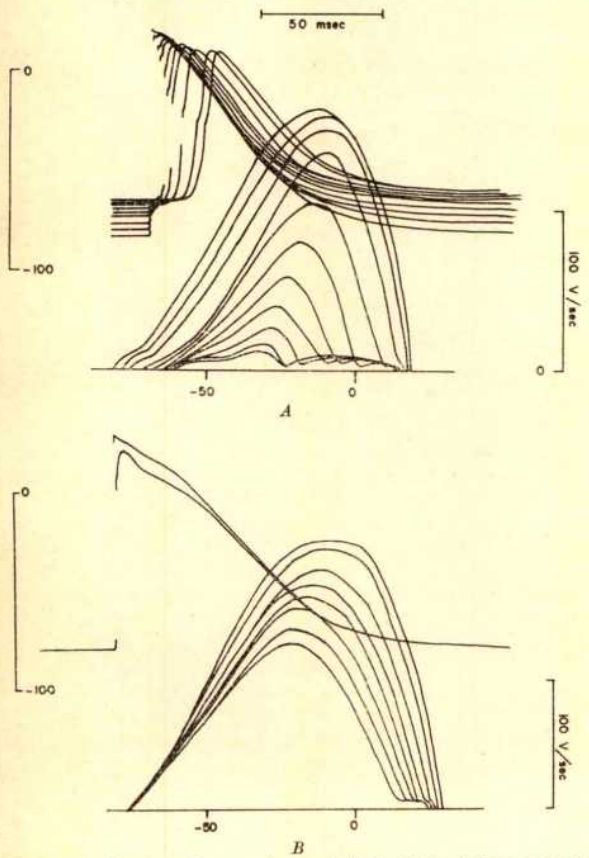

Fig. 3. *A*, Transmembrane action potentials obtained from a single atrial fibre of an electrically driven isolated rabbit heart preparation. Tracings of records showing the effects of local application of potassium-rich solution. Above are shown changes in transmembrane potential as a function of time and, below, the rate of change of potential as a function of voltage during the upstroke. The voltage calibration applies to the upper traces and represents 100 mV; the abscissa for the lower traces shows potential in mV. Note that, although there is a marked decrease in the maximum rate and magnitude of depolarization due to the initial fast component, the time course and magnitude of depolarization due to the slow component remain essentially unchanged. *B*, Tracings of records, as in *A*, showing the effects of local ejection of a sodium-depleted (95 per cent) medium. Effective sodium concentration at recording site is higher than in the ejected fluid due to its dilution in the surrounding medium. Note the small changes in peak potential and duration. See text for description.

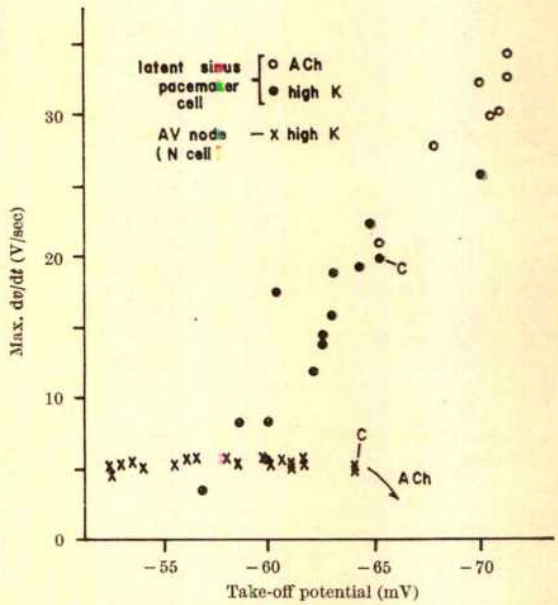

Fig. 4. Plot of maximum rate of rise (max. dv/dt) in V/sec, against resting potential before excitation (take-off potential), in mV. Circles depict data obtained from a latent sinus pacemaker cell which exhibited an initial fast component similar to that shown in Fig. 1*C*. Crosses relate to data obtained from an atrioventricular nodal *N* cell, like the one shown in Fig. 1*D*. Note that depolarization leaves practically unaltered the rate of rise of the slow component upstroke of the nodal cell. C, Control.

and in the amplitude of the depolarization due to the initial fast component. Sodium depletion, however, has a much smaller effect on the slow component as is shown by the minimal change in its peak potential (Fig. 3*B*).

The findings which we have summarized suggest to us that two distinct and different mechanisms may be responsible for depolarization of cardiac muscle or for the development of the cardiac action potential. The first mechanism is probably the voltage dependent and regenerative increase in sodium conductance which has been shown to be the cause of the action potential upstroke in the squid giant axon[8] and other excitable tissue. In atrial, ventricular and Purkinje fibres this mechanism is the cause of the rapid phase of the upstroke of the action potential, and its transient nature accounts for the voltage-time variation of the fast component. It shows the expected dependence on transmembrane potential and extracellular sodium concentration, but is not directly influenced by ACh. The second mechanism is sensitive to ACh and is relatively uninfluenced by changes in membrane potential; it is less sensitive to a decrease in extracellular sodium concentration. This mechanism appears to be the sole cause of the slowly rising action potentials

recorded from true nodal fibres. It also contributes the plateaux of the action potentials of Purkinje, atrial and ventricular fibres and is responsible for the final slow portion of the upstroke of perinodal fibres. We have no direct evidence concerning the nature of the mechanism underlying the slow components; however, its sensitivity to ACh suggests that it may be a decrease in potassium conductance. This hypothesis is supported to some extent by the fact that the apparent resistance to weak current pulses applied through microelectrodes is markedly reduced only during the fast component. This holds true even when the fast component constitutes a minor part of the upstroke of the action potential; in such cases, the polarization resistance is high for the remainder of depolarization[9].

Whatever mechanism is responsible for the slow component, it is apparent from the peculiar behaviour of sinoatrial and atrioventricular nodes[10] that its appearance in isolation imposes electrophysiological characteristics on these tissues which may differ markedly from those observed in the presence of the fast component.

REFLEX INNERVATION OF THE TEMPORO-MANDIBULAR JOINT

By B. E. GREENFIELD* and DR. BARRY WYKE†
Neurological Laboratory, Department of Applied Physiology, Royal College of Surgeons of England, London, W.C.2

THE neurology of the temporo-mandibular joint has never been adequately investigated, despite its obvious importance to dental physiologists and surgeons. It is not generally appreciated, for example, that many of the functional hypotheses of orthodontic surgery relating to this joint[1] are merely inferential, and are not founded on any systematic experimental knowledge of its innervation. Appropriate clinical investigations, however, over the past 10 years suggest that its nerve supply probably contributes to the reflex regulation of the masticatory musculature[2–5] and to mandibular kinaesthetic perception[6]. In order to remedy this situation, we have examined the innervation of the temporo-mandibular joints in twenty cats with macroscopic, microscopic and neurophysiological techniques similar to those used previously in this laboratory for the investigation of the knee[7], ankle[8] and laryngeal[9,10] joints.

Extrinsic articular innervation. Both macrodissection and microdissection studies show that the innervation of the temporo-mandibular joint in the cat is provided[11] from articular branches of the auriculo-temporal, masseteric and deep temporal nerves, in a pattern similar to that in man[6,12]. The joint is not innervated from the facial nerve.

The auriculo-temporal nerve supplies the posterior and postero-medial aspects of the joint capsule and the related articular fat pad as it curves behind the joint. Further articular branches are provided to the lateral capsule and ligament of the joint as the more distal part of the nerve crosses the ramus of the mandible below the joint, ascending (deep to the masseter muscle) in the periosteum covering the lateral surface of the ramus. The masseteric nerve gives off numerous articular branches which form a plexus on and within the anterior capsule of the joint, as the nerve passes through the sigmoid notch of the mandible to innervate the masseter muscle. The deep temporal nerves, which innervate the temporalis muscle, give off variable articular branches within the substance of the muscle that pass from its deep surface to the anterior and anteromedial aspects of the joint capsule.

Articular nerve endings. Neurohistological examination (in gold chloride, frozen and paraffin silver and methylene blue preparations of fresh tissue) of the terminations of the articular nerves in the capsular, ligamentous, synovial, meniscal and adipose tissues of the temporo-mandibular joint reveals that the nerve endings are similar in type to those in the limb joints[7,8,11]. In terms of the relative numerical proportions of the different types of ending (*q.v.*), the temporo-mandibular joint is more like the ankle[8] than the knee[7] joint.

Myelinated afferent fibres of medium (6–12μ) diameter in the articular nerves terminate in clusters of encapsulated Type I and Type II corpuscles[5,7,13] embedded in the fibrous capsule on all aspects of the temporo-mandibular joint. The population density of these end organs is greatest posteriorly and postero-laterally, and least in the medial part of the joint capsule. As in the limb joints[13], the fibres innervating the Type II corpuscles are larger than those innervating the Type I corpuscles (8–12μ compared with 6–9μ). Type II corpuscles are also present in large numbers in the fat pad situated posterior to the temporo-mandibular joint, as is the case with articular fat pads elsewhere in the body[7,8,13]. Larger (up to 17μ in diameter) myelinated afferent fibres, located mainly in the articular branches of the auriculo-temporal nerve, innervate Type III corpuscles located on the superficial surface of the lateral capsular ligament: these end organs are identical with those located in joint ligaments elsewhere[5,7,8,13].

The many unmyelinated and small (less than 5μ) diameter myelinated fibres present in all the articular nerves terminate in plexuses and free nerve endings that are distributed throughout the fibrous capsule and the posterior fat pad related to the joint, and in the walls of the articular blood vessels. These unorganized terminals constitute the Type IV variety of articular nerve ending[5,13] and are identical with those in other joints[7–10].

No nerve endings are present in the synovial tissue of the temporo-mandibular joint, as is the case with all other joints[7–10,13]. Likewise, there are no nerve endings of any type in the joint meniscus[4,11,14], apart from some Type IV terminals distributed in the most peripheral fibrous layers of the disk at the points where it is attached to the joint capsule—as is the case with the menisci in the knee joint[7,13].

Neurophysiological investigations have shown[5,8,10,13,15] that in all joints the corpuscular end organs are mechanoreceptors with differing behavioural characteristics. Discharges from Type I corpuscles are slowly adapting and from Type II corpuscles rapidly adapting, in response to changing mechanical stresses in the tissues in which they lie; both types of corpuscle have relatively low thresholds. The Type III corpuscles in the joint ligaments are high threshold, slowly adapting mechanoreceptors that are activated only at the extremes of joint movement. The non-corpuscular Type IV terminations provide the articular pain receptor system[4,5,7–9,13].

Articular mechanoreceptor reflexes. The reflex influence of discharges from the Type I and Type II mechanoreceptors in the temporo-mandibular joint on the masticatory muscles was examined in multichannel electromyographic investigations of motor unit activity in these muscles during passive movements of the isolated temporo-mandibular joint, using cats under light monitored pentobarbitone anaesthesia. The experimental procedure was similar to that used in this laboratory for the demonstration of articular reflexes in the larynx[10] and at the ankle[8].

After inducing anaesthesia, all the supra- and infra-mandibular muscles were detached at their insertions from one half of the mandible—care being taken to preserve the articular and muscular branches of the related nerve trunks. Pairs of fine, stainless steel electrodes (insulated except at their tips) were then inserted into the temporalis, masseter and pterygoid muscles on each side of the head, from which simultaneous bipolar electromyograms were recorded on a Grass polygraph. An insulated brass rod was wired to the left horizontal ramus of the mandible; this rod was manipulated between stop bars to produce measured passive movements of the mandible in opening, closing, protrusive, retrusive and side-to-side movements (the latter with the mandible in the open and in the closed, but not dentally occluded, position), after immobilization of the animal's skull and body in the prone position by attachment to a brass scaffold bolted to the operating table. The degrees of jaw movement were measured with a transparent protractor on enlarged photographs of the movement, made with an electronic flash camera. In some experiments, the mandible was left intact so that both sides were moved simultaneously, the muscular activity on the intact side being used for synchronous comparison with that on the operated side; in others, the symphysis menti was divided and each half of the mandible was moved independently—the other side being immobilized by fixation to the scaffold. In various experiments, simultaneous records were made of the animal's electrocardiogram, electroencephalogram, respiratory movements, pulmonary ventilation and limb muscle activity for monitoring purposes. The animals were kept warm on a thermostatically controlled, heated operating table.

Preliminary investigations showed that the basic patterns of muscular activity during each of the passive jaw movements listed, performed with the muscles intact, are similar in the lightly anaesthetized cat to those associated with comparable voluntary jaw movements in man[2,3]. After the muscles had been detached on one side, reciprocally related facilitation and inhibition of motor unit activity could still be provoked (although at lower amplitude) in the detached muscles by movements of the ipsilateral temporo-mandibular joint, even though occlusion of the teeth was avoided during such movements. In these circumstances the muscular responses to passive movement cannot arise from myotatic or dental receptors, and for this reason they must be evoked by discharges from the mechanoreceptors in the capsule of the moving temporo-mandibular joint. Furthermore, analysis of the electromyograms shows that the motor unit responses thus provoked fall into two categories—rapidly adapting (within 1·5 sec or less) effects that occur only at the onset of movement, and slowly adapting effects that develop during movement and persist at lower intensity throughout maintenance of the new jaw position. The characteristics of these responses are totally different from the very slowly adapting myotatic reflex responses produced in response to direct stretch of the detached muscles, but are identical with the rapidly and slowly adapting articular reflex responses previously demonstrated in the muscles of the limbs[8] and larynx[10].

Confirmation of the articular origin of the residual motor unit responses to mandibular movement in the detached jaw muscles is provided by the following additional observations that were made in these experiments.

(1) The responses to all movements were reversibly abolished, in the detached muscles only, for periods of 50–60 min by infiltration of the capsule of the ipsilateral temporo-mandibular joint with a local anaesthetic solution (1 per cent lignocaine hydrochloride)—as is the case with other articular reflexes[8,10,15]. In this respect, it may be noted that local anaesthesia of the temporo-mandibular joint also produces impaired mandibular positioning in man[6].

(2) The responses to all movements were irreversibly abolished, in the detached muscles only, by electrocoagulation of the capsule of the ipsilateral temporo-mandibular joint—as is again the case with other articular reflexes[8,10,15].

(3) The responses to all movements were irreversibly abolished, in the detached muscles only, by ipsilateral condylectomy or disarticulation of the ipsilateral temporo-mandibular joint.

(4) Similar responses could be provoked in the detached muscles (in the absence of jaw movement) by direct traction on the residual capsule of the ipsilateral temporo-mandibular joint after removal of the head of the mandible from the joint cavity.

(5) As is the case in the limbs[8], the articular reflex responses in the jaw muscles are abolished selectively by a slight increase in the degree of general anaesthesia, at a stage when the direct myotatic reflexes in the same muscles remain unimpaired. They return when anaesthesia is allowed to diminish again, but are totally absent as long as anaesthesia is maintained at the stages customarily used for surgical procedures.

The last of these observations (with others) suggests that the articular mechanoreceptor reflex system related to the temporo-mandibular joint is polysynaptic, in contrast to the monosynaptic nature of the masticatory myotatic reflex arc[16]. Articular reflex systems related to other joints are polysynaptic[8,10,15]; and preliminary microelectrode recordings of the potentials evoked in the lower brain stem nuclei by passive movements of the jaw in cats[17] add further support to the view that they are likewise polysynaptic in relation to the temporo-mandibular joint.

These investigations demonstrate that the articular tissues of the temporo-mandibular joint are liberally provided with rapidly and slowly adapting corpuscular mechanoreceptors, and with an elaborate non-corpuscular pain receptor system. They further show that discharges from the articular mechanoreceptors make significant contributions (both facilitatory and inhibitory) to the reflex co-ordination of masticatory muscle activity during jaw movements in all directions. Clearly, then, changes in temporo-mandibular articular reflex activity must now be considered as contributing to the production of various clinical types of abnormal jaw relationships and to the variety of masticatory responses to different types of orthodontic treatment.

We thank Johanna Gitau, C. Redman and K. McCarthy for assistance in the conduct and photography of these investigations.

IMMUNOLOGICAL DETERMINATION OF HUMAN FOLLICLE STIMULATING HORMONE

By ANNELIESE WOLF*

United Birmingham Hospitals, The Women's Hospital, Department of Clinical Endocrinology, Showell Green Lane, Sparkhill, Birmingham, 11

ALTHOUGH immunoassays for human chorionic gonadotrophin (HCG) and human pituitary luteinizing hormone (LH) have been described[1], similar assays for human follicle stimulating hormone (FSH) have not yet been reported. The reason for this is probably the lack of a specific antiserum. Recently there have been a number of reports on haemagglutination-inhibition experiments using antisera raised to human pituitary FSH preparations[2,3], but correlations of biologically and immunologically determined FSH were not demonstrated.

Extensive investigations in this laboratory[4] have shown that antisera to human pituitary FSH fractions neutralized the biological activity of FSH but contained immunological contaminants, notably to albumin and to an antigen common to most preparations of HCG. The interference from these contaminants in haemagglutination-inhibition tests could be largely removed by absorption with albumin and HCG, but the estimations of FSH activity remained unreliable and there were possibly still other immunological contaminants. New methods of removing these contaminants were recently reported[5]. This article describes haemagglutination-inhibition tests carried out for FSH with two antisera raised against the purified preparations.

Human pituitary FSH was prepared as previously described[6], and was purified by partitioning in the system urea: ammonium sulphate : ethyl 'Cellosolve' and electrophoresis on starch gel. The solutions used for immunization contained about 400 mg IRP-HMG (international reference preparation of human postmenopausal gonadotrophin), that is, 57 I.U. FSH/ml., and showed no detectable LH activity by the ovarian ascorbic acid depletion method, or albumin by the haemagglutination-inhibition test. Other human pituitary FSH preparations were fractions obtained at various stages of the extraction procedure. Human pituitary LH fractions were kindly supplied by Dr. A. S. Hartree, Cambridge[7]. Samples of urinary FSH materials were mainly stock preparations of this laboratory, obtained either from the urine of postmenopausal women (HMG) or from the urine of normal menstruating women by means of kaolin absorption and reprecipitation from ammonium acetate solutions with alcohol. Other urinary extracts (Fig. 3) were prepared from daily collections of early morning specimens of urine, when 20 ml. of urine were precipitated by benzoic and tungstic acids[8], washed in alcohol and ether and finally dissolved in 0·5 ml. of saline to make a fortyfold concentrate of the original urine. In all immunological determinations, HMG 613 (N.V. Organon–Oss, Holland) was used as standard preparation.

Inoculations were carried out by combining intramuscular injections of antigen suspended in Ramon's adjuvants with intravenous injections of antigen adsorbed on to bentonite. The total amount of antigen given to one animal was approximately equivalent to 6 g IRP-HMG.

Two antisera obtained from two rabbits showed similar although not identical properties. After absorption with normal human serum they completely inhibited the action of the equivalent of 3 mg IRP-HMG when given to immature mice in doses down to 0·0012 ml. In agar diffusion and immunoelectrophoretic experiments, the two antisera formed two precipitin lines with most human pituitary and urinary FSH preparations. One of the lines —that which occurred in the albumin position—was not observed when albumin-free HMG 613 was used as antigen. LH did not form a precipitin line with one of the antisera but, when added in increasing amounts to the antiserum as an absorbent, one of the two lines formed with FSH was progressively removed. Precipitin lines formed with HCG were weak with either antiserum.

The haemagglutination-inhibition method was used for quantitative immunological estimations. Sheep red cells were tanned and later coated with a 'Cellosolve' partition fraction of human pituitary FSH because the most purified fractions of starch gel did not appear to become sufficiently firmly attached to the cells. The coating was performed by incubating 1 ml. of a 10 per cent suspension of tanned cells with 100 μg antigen for 1 h at 37°–40° C.

Comparisons were made between the biological activity of several preparations as tested by the ovarian augmentation assay and immunological activity using a human pituitary FSH haemagglutination system. All results were expressed in terms of IRP-HMG. Fig. 1 shows FSH determinations of ten consecutive collections of urines over a period of 72 h from a female patient. The pattern of the biological activity of the extracts is reflected fairly well in the pattern of the immunological results although the reflexion is not quantitatively precise.

Fig. 2 shows the degree of correlation between the biological and immunological estimations of FSH activity of twelve HMG extracts, one extract from specimens of urine from a menstruating woman and six human pituitary extracts. In order to calculate the mean immunological values with upper and lower limits, the method developed by Butt *et al.*[1] was applied. Except for those few urinary extracts with low biological activity which showed no immunological activity up to 5 mg/ml., only crude acetone dried pituitary powder gave a largely misleading immunological result. The majority of biological and immunological figures were of the same order within each pair (Table 1). Because crude pituitary powder contains LH as well as FSH, purified fractions of LH were next studied. It was found that they reacted strongly in this system—the results did not correlate with either the LH activities or the FSH activities of the fractions (Table 2).

* The conversion factor from mg IRP-HMG to I.U. HCG was 0 31 (obtained from Dr. Butt).

In Fig. 3, only immunological FSH estimations are shown. Daily specimens of morning urine for three consecutive menstrual cycles were pooled into ten specimens per cycle. The urines were collected by a patient for a control month and then for 2 months while she was taking contraceptive pills. There was not enough urine to carry out bioassays; however, the pattern of the control month fits well into the patterns obtained by bioassays on FSH changes during the menstrual cycle[9]. During the 2 months the patient was on contraceptive pills the release of FSH was largely suppressed.

In contrast to antisera which had been raised to human pituitary FSH fractions on previous occasions and had not

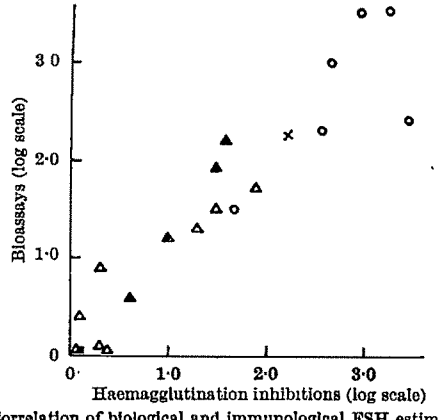

Fig. 2. Correlation of biological and immunological FSH estimations of human pituitary FSH preparations (○), crude HMG preparations (△), purified HMG preparations (▲) and a urinary extract of a menstruating woman (■). HMG 613 standard (×).

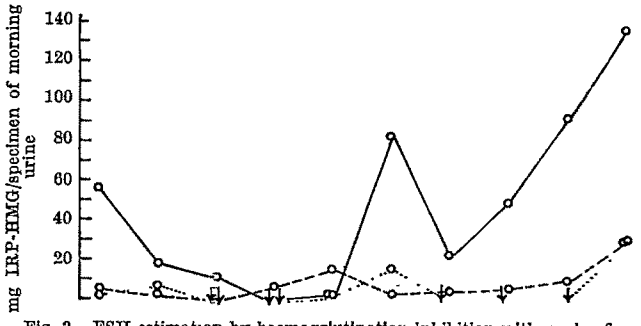

Fig. 3. FSH estimation by haemagglutination inhibition with pools of urines of three consecutive menstrual cycles. Control month (———), first month on contraceptive pills (– – –), second month on pills (·····).

been treated with organic solvents and urea, the antisera reported here readily reacted with urinary FSH preparations in the haemagglutination technique. The correlation between the figures obtained for the biological and immunological activities of pituitary and urinary FSH is fairly good, although the reason for the strong interference of LH remains obscure. It was found that, in terms of I.U., HCG had a much less pronounced inhibitory effect than LH, and that LH preparations did not react according to their biological activities. The results of the experiments suggest the presence of an unspecific immunogenic component originating from the pituitary and which is common to both LH and FSH preparations. This suggestion is supported by two further observations. First, although the FSH fractions used for inoculation contained no LH activity which was biologically detectable, it was impossible to absorb the antisera by LH without losing a large proportion of the haemagglutination titres. Secondly, it was observed that a crude extract from acetone dried pituitary powder and an LH fraction which showed comparatively little biological activity exhibited a particularly strong inhibitory effect in haemagglutination tests. It is therefore clear that in certain circumstances misleading results may occur; however, in view of the correlation shown for both biological and immunological determinations of FSH, it is unlikely that the unspecific component interferes in a misleading way when immunological investigations are carried out on purified preparations of FSH. This is also true when the investigations are carried out on extracts of body fluids which have been submitted to an identical extraction technique. It is possible that the component is present at a consistent ratio in such extracts.

It can be concluded that the precision of the haemagglutination assay for FSH is limited. However, this appears to apply to similar assays of other protein hormones as well as for HCG[10]. Nevertheless, the method may be helpful for overall checks in clinical work.

I thank Dr. A. C. Crooke for encouraging this work and Dr. W. R. Butt for the numerous fractions of FSH of known potency, especially prepared for this investigation. I also thank Dr. F. Ingrassia, Florence, for some of the urinary extracts, and Organon for their gift of HMG 613. This work was carried out under a grant from the Medical Research Council.

LEUCOANTHOCYANINS FROM THE LEAVES OF EUROPEAN LARCH (*Larix decidua*, MILL)

By DR. H. G. C. KING
Rothamsted Experimental Station, Harpenden, Hertfordshire

WHILE investigating the mobilization of iron by aqueous extracts of leaves which had fallen during the autumn from various species of trees, I noted that a dilute aqueous extract of larch leaves, kept at 0° C for a week, deposited a precipitate with properties typical of a leucodelphinidin. The slight mobility of the product on paper chromatograms, in both aqueous and organic solvents, indicates that it is not a monomeric leucoanthocyanin. The structure of the leucodelphinidin has not been investigated in detail, but its unusual nature, and that of the unknown leucoanthocyanidin described here, seem to warrant a preliminary report of their properties.

There are few published accounts of the chemistry of the leaves of *Larix decidua*. That of Brown *et al.*[1], who described the formation of delphinidin and cyanidin when leaves are heated with concentrated hydrochloric acid, is relevant to the present work. They found that a streak of small mobility in aqueous chromatographic solvents exhibited the properties of a leucoanthocyanin.

Larch Leaf Leucodelphinidin

Larch leaf leucodelphinidin, accompanied by a water insoluble organic calcium compound, separates at 0° C from aqueous extracts containing about 20 per cent dry matter, or from more concentrated extracts at room temperature. Larger quantities can be obtained by further concentrating the filtrate. The total yield of leucodelphinidin and the calcium compound varies with samples gathered in different years; it is usually 2–3 per cent of the dry weight of milled leaves, and it remains unaffected whether the leaves are dried by freezing or heating in an oven after collection. Approximately equal amounts of the leucodelphinidin and the calcium compound are present in the alcohol-washed and dried precipitate. The leucodelphinidin is difficult to purify, but a sample which can be shown to be homogeneous by chromatography can be prepared by stirring the crude precipitate with ten times its weight of water, filtering, evaporating the filtrate to dryness *in vacuo* and washing the residue with methanol. The final product is amorphous, and has a melting point $<350°$ C. The calcium compound is insoluble in water and in methanol. It has no reducing properties but reacts strongly with Morris's anthrone reagent[2].

On two-way paper chromatograms the leucodelphinidin moves as a streak with a rate of flow (R_F) of 0–0·5 in 6 per cent acetic acid, and also as a streak with an R_F of 0–0·12 in Forestal solvent (acetic acid/water/concentrated hydrochloric acid, 30 : 10 : 3 v/v) (ref. 3), but is immobile in organic chromatographic solvents. The streak reacts with the ferricyanide reagent[4] and becomes pink when heated after spraying with either 2 N aqueous hydrochloric acid or 3 per cent alcoholic toluene *p*-sulphonic acid[5]. An aqueous solution of the leucodelphinidin becomes brown on adding 3 per cent ferric chloride.

Delphinidin is formed when the leucoanthocyanin is heated at 100° C with *n*-butanol/concentrated hydrochloric acid (20 : 1 v/v)—this can be confirmed by spectrophotometry and paper chromatography with Forestal solvent, 90 per cent formic acid/hydrochloric acid 3 N (1 : 1 v/v) (ref. 6) and *n*-butanol/acetic acid/water (6 : 1 : 2 v/v). After extracting the delphinidin, glucose and arabinose can be detected in the aqueous hydrolysate by paper chromatography with water-saturated phenol and *n*-butanol/acetic acid/water (6 · 1 : 2) (ref. 7).

Visual comparison of the chromatograms with standards and spectrophotometric determination[8] of the sugars extracted from the excised spots indicate a molecular ratio of 1 : 1 for the two sugars. The presence of 16 per cent glucose, determined directly on various samples of the leucodelphinidin with anthrone[2], with which arabinose does not react, indicates a molecular weight of about 1,200, assuming that the compound contains one molecule each of glucose and arabinose.

The ultra-violet absorption spectrum of the leucodelphinidin in water shows little absorption throughout the range 200–400 mμ, with a broad maximum between 260 mμ and 280 mμ, $E^{1\%}_{1\,cm}$ (275 mμ) = 19. The spectrum in 0·1 M aqueous sodium hydroxide shows no maximum, only a flattening of the curve between 275 mμ and 285 mμ. It seems that the leucoanthocyanin is probably a polymeric leucodelphinidin in which one or more of the vicinal hydroxyl groups in the pyrogallol ring is masked, possibly by the sugar residues, leading to a loss of reactivity to ferric chloride.

The existence of true leucoanthocyanins, that is glycosides of leucoanthocyanidins, has seldom been reported. Shantz and Steward[9] claim to have isolated such a monoglucoside from the liquid endosperm of *Aesculus woerlitzensis*. Swain and Bate-Smith[10], and Swain[11], suggest that, in general, some polysaccharide may be entrained in the course of extracting a complex leucoanthocyanin, or that the sugar is in the form of a polymer on which the phenolic substance is adsorbed. This seems not to be so with the larch leucodelphinidin, which is isolated as a coprecipitate with the unknown calcium compound from a dilute aqueous extract in which polysaccharide would be expected to remain in solution. In these circumstances, the high glucose content (16 per cent), plus the arabinose, makes the possibility of entrainment or adsorption unlikely.

Anthocyanidins from Larch Leaves

Larch leaves do not contain free anthocyanins and anthocyanidins, but a treatment whereby the leaves are boiled for 30 min with alcoholic hydrochloric acid extracts delphinidin, cyanidin and an unknown anthocyanidin. The last-mentioned compound has very different chemical properties from any natural anthocyanidin so far reported and would seem to be derived from a new type of leucoanthocyanin or leucoanthocyanidin.

Extracts prepared by repeatedly treating larch leaves with cold water give successively smaller amounts of these anthocyanidins when heated with alcoholic hydrochloric acid. The amount increases again when the partially extracted leaves are extracted with hot water. Although it is not known whether the delphinidin prepared from these extracts is derived from a common leucoanthocyanin, the solubility of the isolated leucodelphinidin (above) differs from that of the leucocyanidin and the unknown leucoanthocyanin, neither of which separates in an insoluble form from a cold-water extract of larch leaves. All these leuco-compounds are contained in the streak (R_F, 0–0·5) in 6 per cent acetic acid, which is always present on chromatograms of fresh aqueous extracts of larch leaves.

The relative proportions of the three anthocyanidins were estimated by heating the dry milled leaves with

Table 1. FORMATION OF ANTHOCYANIDINS FROM PICKED (GREEN) AND FALLEN *L. decidua* LEAVES

Sample	Wt. of leaves (g)	E_{max}* (550 mμ)	E_{max}/100 mg oven-dry leaf	Anthocyanidin (per cent)
Fallen leaves (1963)	0·521	0 845	0·162	1·70
Fallen leaves (1963) after cold-water extraction	0 419	0·413	0 099	1·05†
Fallen leaves (1964)	0 588	0 955	0 163	1·80
Picked leaves (1964)	0·516	0·437‡	0 085	0 89

* Calculated as cyanidin, E = 0·477 for a 0·1 per cent solution in *n*-butanol/concentrated hydrochloric acid (20 : 1 v/v). Test solutions made up to 50 ml. and diluted 1 . 10.

† Represents 62 per cent anthocyanidin unextracted by cold water.

n-butanol/concentrated hydrochloric acid (20 : 1 v/v) in a closed tube for 30–35 min[12], and separating the anthocyanidins as bands on Whatman No. 3 paper before spectrophotometric examination. Absorbances (in *n*-butanol/concentrated hydrochloric acid 20 : 1 v/v) are: delphinidin, E = 0·662 (558–560 mμ); cyanidin, E = 0·239 (550 mμ), measured at the wavelengths of maximum absorption on a Unicam *SP* 500 spectrophotometer, giving a ratio of delphinidin : unknown anthocyanidin : cyanidin of 2 : 1 : 0·36. The total amount of anthocyanidin formed was also estimated by measuring E_{max} of a suitable dilution of the original hydrolysate, basing the measurement on the absorbance of pure cyanidin of known concentration[12] (Table 1).

The unknown anthocyanidin can be prepared on a larger scale by distilling off the solvent from the hydrolysate (50 ml.) from 5 g leaves and extracting the residue with 2 N hydrochloric acid. This extract is chromatographed on a column of 'Solka Floc' powdered cellulose with Forestal solvent as eluent, and purified by banding the crude unknown anthocyanidin on thick paper and chromatographing with 90 per cent formic acid/3 N hydrochloric acid (1 : 1 v/v).

The unknown anthocyanidin also differs in its chromatographic behaviour from any anthocyanidin so far reported; in Forestal solvent, the R_F is 0·75 (R_{Cy} = 1·42); in 90 per cent formic acid/3 N hydrochloric acid (1 : 1 v/v), the R_F is 0·29 (R_{Cy} = 1·29); in *n*-butanol/acetic acid/water (6 : 1 : 2 v/v), the streak R_F is 0·63–0·90. When exposed to ammonia vapour its spot, originally similar in colour to cyanidin, changes to green, in contrast with the blue of the common anthocyanidins; the green colour persists for at least 1 h for papers run in Forestal solvent. When the anthocyanidin is taken to dryness from a methanol/hydrochloric acid solution it does not re-dissolve in methanol alone; a blue-purple suspension forms and a drop of concentrated hydrochloric acid is needed for complete solution and return of the usual red colour.

In Robinson and Robinson's qualitative tests[13]: (*a*) the colour of the anthocyanidin in *iso*-amyl alcohol is partly destroyed by oxidation and becomes orange yellow; (*b*) an *iso*-amyl alcohol solution becomes blue on adding sodium acetate, and is unchanged on adding ferric chloride; (*c*) at least 15 volumes of benzene are required to transfer the colour of an *iso*-amyl alcohol solution (1 vol.) to 0·5 per cent aqueous hydrochloric acid (3 vol.) and when the benzene is added, the upper layer of mixture changes colour to blue. The aqueous hydrochloric acid layer becomes pink, however, and the anthocyanidin can be re-extracted unchanged by *iso*-amyl alcohol. When dissolved in lower alcohols containing hydrochloric acid, the colour of the anthocyanidin resembles that of cyanidin.

In the visible region the absorption spectrum of the compound is characteristic of an anthocyanidin having at least two adjacent —OH groups in the *B* ring, that is λ_{max} (0·01 per cent methanolic hydrochloric acid)[14] is at 540–542 mμ, shifting +28 mμ on adding ethanolic aluminium chloride[15]. In *n*-butanol/concentrated hydrochloric acid (1 : 1 v/v) λ_{max} is at 456 mμ. The ultraviolet absorption spectrum between 200 mμ and 400 mμ shows a series of shoulders at 250–255 mμ, 298–308 mμ and 345–354 mμ.

The leucoanthocyanins of larch leaves must be regarded as major constituents of the aqueous extract; the leucodelphinidin, isolated as a precipitate, with the unknown calcium compound together make up 10–15 per cent of the dry matter of the extract.

NON-ASSOCIATIVE BEHAVIOURAL MODIFICATIONS IN NEREID POLYCHAETES

By DR. S. M. EVANS

Department of Zoology, University of Bristol

THERE is no doubt that nereid polychaetes are capable of learning in at least some situations. Habituation is usually regarded as the simplest type of learning, and in the three nereids so far investigated—*Nereis diversicolor*, *N. pelagica*, and *Platynereis dumerilii*—the withdrawal response habituates to repeated stimulation[1–3]. Habituation of this response is, however, probably a complex central process. It has been shown that both the sensory giant axon synaptic junctions and motor giant axon junctions are capable of accommodating to repeated tactile and electrical stimulations in *N. virens*[4] and to sudden changes in illumination in *N. diversicolor*, *N. virens* and *P. dumerilii*[5]. Habituation cannot, however, be attributed solely to motor fatigue, or to accommodation of synapses on the motor side of the reflex, because worms which have habituated to one stimulus are still capable of responding if the nature of the stimulus is changed[2]. Similarly, sensory accommodation cannot account for the habituation process because one response is often replaced by a different one; withdrawal responses, for example, which always occur in response to initial anterior stimulations in *N. diversicolor* and *P. dumerilii*, are sometimes replaced by a response in which the worms attack the seeker used to stimulate them[6].

Four types of associative learning have been investigated in nereids, but the only evidence that these animals can learn associations comes from their behaviour in "T" mazes. If worms which make a "correct" choice in the maze are allowed to remain in a darkened compartment for at least five minutes, they are able to learn to

avoid the punishment in the "incorrect" arm to a criterion of ten consecutive "correct" choices. *N. virens* did this in an average of 68·2 trials, *N. diversicolor* in 85·5 trials, and *Perinereis cultrifera* in 85·0 trials[7]. In a subsequent investigation *N. diversicolor* reached the same criterion in an average of 84·4 trials[8].

The reason for regarding maze learning as a manifestation of associative learning is that higher animals undoubtedly learn to select one arm of a maze by associating some feature of it with a reward or avoidance of a punishment. Nereids in the mazes were not learning in this manner, however, because no clues were provided. It is possible that they are able to learn the maze because the anterior sense organs are stimulated differently when left and right choices are made and, in fact, removal of the anterior sense organs does disrupt a previously learned habit[8]. But proprioceptive sensory information may be used in some circumstances, because almost completely deafferentiated worms can still learn to avoid the punishment[8].

Investigations of the earthworm have indicated that unilateral stimulation given outside the maze can induce a turning preference when earthworms are introduced into a maze[9]. Sessions of unilateral tactile stimulation and stimulation from a bright light induce turning away from the side stimulated and weak illumination induces turning towards the side stimulated. It was suggested that the establishment of the habit of turning in a given direction may be considered as a type of pseudo-conditioning in earthworms—the unconditioned stimulus eliciting a given direction of turning, which is made apparent when the animals are forced to make a turning choice in a maze[9]. But the punishment is not given unilaterally to either earthworms or nereids in the maze-learning situation, and in any case it is well known that nereids do not react in this way to unilateral tactile stimulation at least[6]. The effect of unilateral stimulation cannot therefore be used to explain the learned behaviour of nereids in the maze. Nevertheless, it does raise the possibility that associative learning may not be the only means by which an animal's behaviour can become modified so that it selects the "correct" arm in a maze.

In three other experimental situations which were designed to investigate the ability of nereids to learn by association, modifications in behaviour were observed, which were the result of non-associative processes, but could be mistaken for associative learning. One instrumental-learning situation and two conditioning procedures have been investigated. In the instrumental-learning situation the worms were given a slight electric shock whenever they reached the exit of a 'Perspex' channel. The intention was to test the ability of the worms to avoid the punishment by refusing to crawl along the channel[10,11]. In one series of conditioning experiments, a sudden change in illumination (conditioned stimulus) was paired with food presentation in order to investigate conditioning of the feeding response[12]. In another series of experiments, designed to investigate conditioning of the withdrawal response, an electric shock was paired with the presentation of food[12]. Normally, associative learning is only possible when there is close temporal contiguity between the conditioned and unconditioned stimuli. It was shown in these experiments, however, that nereids learn just as effectively if the unconditioned stimulus is presented between trials as when it is paired with the conditioned stimulus; furthermore, apparent conditioning can sometimes be induced by a single presentation of the unconditioned stimulus. There is little doubt that, in these instances, the behaviour of the worm was modified non-associatively by the sensitization effects of the unconditioned stimulus; that is to say, the behaviour of the worms was modified by the punishment they received with the result that the animals now reversed or remained stationary in the 'Perspex' channel—either course of action enabled them to avoid the shock given at the exit (Fig. 1).

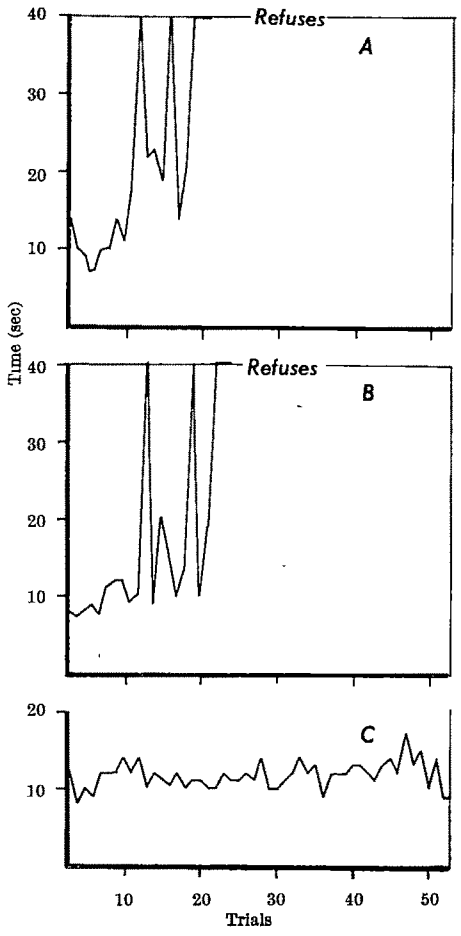

Fig. 1. Time taken for individual *Nereis virens* to crawl to the end of a 'Perspex' channel *A*, Punishment between trials (when the worm is not in the apparatus); *B*, punishment at the exit of channel; *C*, no punishment. (In part after Evans (ref. 10).)

In the conditioning experiments it was found that feeding modified the behaviour of the worms so that they crawled to the ends of the glass tubes containing them in response to sudden changes of illumination and electric shocks. It was noted that tactile stimuli induced greater reactivity of the withdrawal response than did sudden changes in illumination. In these situations the behaviour of the worm can be regarded as learning in the sense that it was modified with experience, but clearly the new habits cannot be considered to have been a manifestation of associative learning.

The chief difference between associative and non-associative learning is the manner in which learning is acquired. Normally, animals are only capable of forming associations under very restricted conditions; for example, conditioned responses can be established by forward conditioning procedures but only with difficulty, if at all, by backward, trace and delayed procedures. Non-associative learning, on the other hand, can be achieved by all these procedures. There are, however, many similarities between associative and non-associative learning and, indeed, it is only with difficulty that the two processes are distinguished. In both processes, the animal's reaction to a stimulus or stimulus situation (conditioned stimulus) becomes modified as a result of the effects of a reward or punishment (unconditioned stimulus) and the modifications can be retained after the new habit has been acquired. Retention of non-associative learning in nereids appears, however, to be short-lived; for example, retention of the habit learned in a 'Perspex'

channel is less than 24 h (ref. 10). The similarities that exist suggest that non-associative learning may be achieved by mechanisms which are not unlike those involved in associative learning; indeed, mechanisms may exist in nereids resembling those which Young[13-15] believes to be involved in associative learning in *Octopus*.

Young suggests that in *Octopus* exploratory responses to unfamiliar objects are elicited by a change in the visual situation. At first the response is weak, but if it is reinforced by a reward the animal responds more rapidly. There is, therefore, a mechanism for producing graduated commands to attack so that the octopus responds quickly to a cue-stimulus which has proved favourable. However, if the cue-stimulus is accompanied by an unfavourable situation—one in which the animal is punished—the tendency to explore or attack the object is reduced. Overall there is a balancing of signals indicating reward or punishment; the tendency to explore is increased by reward and reduced by punishment. Young believes that visual learning in *Octopus* is controlled by the vertical and median superior frontal lobes of the brain. He suggested that the vertical lobe is a centre that tends to reduce the tendency to attack if the animal is punished, and that the median superior frontal lobe tends to promote it if the animal is rewarded. This view is supported by experimental evidence; in some cases, at least, it is found that removal of the vertical lobe in *Octopus* increases the tendency to attack (removes the inhibition) and removal of the median superior frontal lobe decreases the tendency to attack[14].

Behaviourally, nereids resemble *Octopus* in the sense that a stimulus is capable of eliciting either a positive or a negative response, depending, at least partially, on the reinforcement the animal has recently experienced. In the laboratory, a nereid reacts to stimuli, such as various chemical stimuli[16], sudden changes in illumination[12], mechanical stimuli[1], and anterior tactile stimuli[17] in one of two ways. It may either react positively, by crawling along the tube which it is inhabiting, often exploring the area adjacent to the mouth of the tube, or negatively, by withdrawing, by reversing in the tube, or by ignoring the stimulus altogether. Sometimes both a withdrawal (negative) response and a positive response may occur to the same stimulus; in this event, withdrawal is always followed by the worm crawling to the end of its tube. Punishment tends to promote negative (avoidance) responses. In the 'Perspex' channel it inhibits movement and facilitates reversal; this enables worms to avoid a punishment at the end of the channel. Punishment given to worms in glass tubes causes the withdrawal response to become more reactive to sudden stimulation. Conversely, reward promotes positive responses; food presentation facilitates exploratory responses to sudden changes in illumination. Thus it would seem that, like *Octopus*, nereids may have mechanisms producing graduated commands for exploratory and avoidance behaviour, which are influenced by the nature of the reinforcement that is received by the animal. If paired centres do exist in nereids, and possess functions similar to those suggested for the vertical lobes and median superior frontal lobes in *Octopus*, it is possible that they are housed in the supra-oesophageal ganglion and sub-oesophageal ganglion. In fact, Prosser[18] has already suggested that in annelids, the supra-oesophageal ganglion may be an inhibitory centre and the sub-oesophageal ganglion an excitatory one.

The functions of the sub-oesophageal ganglion in annelids are difficult to evaluate from extirpation experiments because removal of this ganglion necessarily disconnects the supra-oesophageal ganglion and anterior sense organs from the rest of the central nervous system. However, extirpation is generally followed by inactivity, which might be predicted if this is an excitatory centre.

Fortunately, removal of the supra-oesophageal ganglion has less drastic effects. Its extirpation does not prevent earthworms from crawling, burrowing, withdrawing, and copulating[19], and similarly decerebrate nereids can withdraw, swim, crawl, irrigate, and burrow[20]. However, both earthworms[21] and nereids[20], deprived of the ganglion, become hyperactive, and decerebrate nereids irrigate their tubes incessantly and more energetically than before[21]. It would appear, therefore, that in the intact animal the supra-oesophageal ganglion is inhibitory at least as regards the performance of certain activities. If the supra-oesophageal ganglion of the annelid acts as a centre that inhibits positive responses and facilitates avoidance responses—which is the suggested function of the vertical lobes in *Octopus*—removal of it should tend to increase positive responses at the expense of negative ones (in *Octopus* removal of the vertical lobes increases the tendency to attack objects[14]). Hess[24] found that after removal of the supra-oesophageal ganglion, the normal negative response of worms in turning away from bright light was reversed. Before extirpation, only nine responses in a total of 144 were turns towards the source of illumination, but after extirpation of the ganglion this increased to 132 out of 144 responses. More recently Ratner and Stein[25] also found that decerebrate earthworms responded positively to sudden increases in illumination more frequently than did intact worms.

Similar functions for the vertical lobes in *Octopus* and for the supra-oesophageal ganglion in annelids are also suggested by the behavioural effects resulting from extirpation of these centres in problems involving avoidance learning. Thus Boycott and Young[26] found that an *Octopus* lacking the vertical lobes could only learn not to attack an isolated crab if there was an interval of only 2 min between trials. Similarly, Wells and Wells[27] found that removal of the vertical lobes made it difficult or impossible for blinded octopuses to learn a tactile discrimination when the intervals between trials was 1 h, although they could do so when this time interval was only 5 min. Furthermore, it has been established that decerebrate nereids are only able to learn to avoid a punishment at the end of a 'Perspex' channel if a massed training technique is used (Fig. 2). In this event the learned response never involves a reversal in the channel; instead the decerebrate worms remain stationary[10]. Similarly, it appears that the withdrawal response of decerebrate earthworms can only be conditioned by massed training[28].

Young[15] suggests that a permanent memory is not actually stored in the vertical lobes in *Octopus*, but that these are only temporarily involved in setting up a memory trace. Nereids are similar in this respect, because although the supra-oesophageal ganglion is not the site of retention (worms trained in an avoidance-learning situation retain the learned response even if they are later decerebrated[10]),

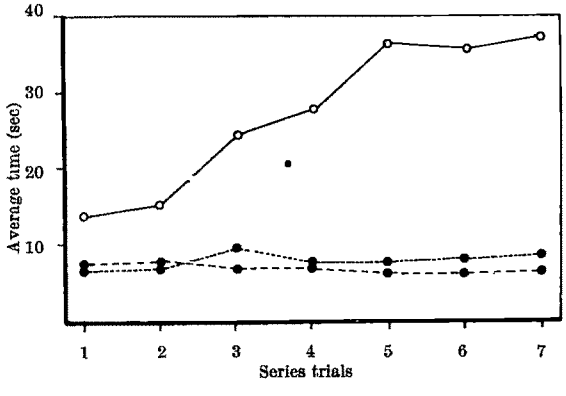

Fig. 2. Learning in intact and decerebrate *Nereis virens* with spaced trials. Average results plotted. ○———○, Intact worms trained in series of ten trials at 30 min intervals. ● – – – ●, Decerebrate worms trained in series of ten trials at 15 min intervals. ●·····●, Decerebrate worms trained in series of ten trials at 30 min intervals. (After Evans[10].)

it is clearly important in the establishment of memory traces. Naive, decerebrate worms are able to learn to avoid th shock at the end of the 'Perspex' channel in about the same number of trials as intact worms, but they are unable to retain the learned behaviour for even 1 h, whereas intact worms can retain it for 6 h (ref. 10).

Although the brain of *Octopus* has been mapped far more thoroughly than the ganglia of any annelid, a certain number of anatomical similarities do exist between the *Octopus* brain and the supra-oesophageal ganglion of annelids. The features of particular interest in the "brains" of many annelids are the corpora pedunculata. These consist of numerous small, globuli cells which resemble the small cells characteristic of the learning centres of cephalopods and vertebrates. Although the functions of the corpora pedunculata of annelids have never been explored, it is quite possible that these are centres concerned with behavioural modifications—particularly in view of the fact that a large proportion of the rest of the supra-oesophageal ganglion is neurosecretory in function.

The major difference between learning in *Octopus* and *Nereis* is that, as Young[13] points out, in *Octopus* the response does not remain "unconditional" and the signals received from either the punishing or rewarding event (the reinforcing signals) condition the distance receptor mechanisms that have been active. In nereids, in at least some learning situations, the mechanism necessary for this conditioning to occur does not exist. The reinforcing signals probably activate all receptor systems non-associatively and association between the reinforcing signals and the receptor system activated is extremely unlikely because a single unconditioned stimulus can modify the behaviour of the worm. For example, one tactile stimulus can induce a withdrawal response to a sudden decrease in illumination in a previously habituated worm, and similarly a single presentation of food can sensitize the feeding response to a sudden increase in illumination[12]. It is a most unlikely explanation of these results to suggest that one-trial learning is occurring, as there is no temporal contiguity between the conditioned and unconditioned stimuli involved.

Associative learning mechanisms of the kind described in *Octopus* may have evolved from non-associative mechanisms such as those in nereids. In both *Octopus* and nereids a reinforcing event has a similar effect on the subsequent responses the animal makes to stimuli, but conditioning mechanisms in *Octopus* have been evolved which enable learned responses to be linked with a particular stimulus situation. Conditioning mechanisms exist in a variety of vertebrates and higher invertebrates and, although they may have evolved independently on more than one occasion, Young[13] has pointed out that there are apparent similarities in the associative learning mechanisms of animals which are as widely separated phylogenetically as mammals and cephalopods. In mammals the situation is undoubtedly extremely complex, but the hypothalamus does contain pairs of centres producing opposite effects and, furthermore, it is linked by pathways to the septum which may contain similar centres. The hippocampus and the amygdaloid nuclei are necessary for the establishment of memory but are not the site of retention. This suggests that these regions of the mammalian brain may have a function similar to that of the vertical lobes in *Octopus*, and it has been found that in mammals bilateral removal of the hippocampus may grossly disturb memory for recent events.

In many animals conditioning mechanisms operate under very restricted conditions and conditioning can only be established if the conditioned (cue) stimulus is closely associated with the reinforcing event (unconditioned stimulus). In many mammals the optimum conditions occur if the unconditioned stimulus occurs 0·5 sec after the onset of the conditioned stimulus[29]. But this is not always so; for pigs the optimum is believed to be 4 or 8 sec[30], and for the rhesus monkey 2 sec[31]. For fish it is also 2 sec[32]. It may be physiologically difficult to associate the conditioned stimulus with the signals of the reinforcing stimulus unless they occur concurrently and in the correct sequence. As Young[13] has pointed out, there is a delay between the receipt of the one stimulus by the nervous system and the reinforcement signals which follow. In order to produce conditioning, the address of the appropriate elements in the memory system must be held during the delay. The delays in holding the necessary information during trace and delayed conditioning procedures may be too great to enable conditioning to occur. In backward conditioning it would be necessary to hold information of the reinforcing event until the receipt of the cue-stimulus. Such a mechanism may well not exist after all, for learning to associate a conditioned stimulus with an event that has already occurred is most probably of no biological value whatsoever.

Conditioning mechanisms have probably evolved with the evolution of sense organs that are capable of making detailed sensory discriminations. Animals such as *Octopus* have well developed sense organs and are capable of accurate sensory discriminations. Consequently they are able to associate one particular, say visual, stimulus with a particular reinforcing event and another visual stimulus with another reinforcing event. Indeed, it appears that they have well developed abilities to do so[33]. Presumably they are also able to learn to recognize both prey and predators and respond accordingly. Animals such as nereids, on the other hand, are almost certainly unable to distinguish between visual stimuli caused by predators and those by food because their eyes are incapable of forming images. A sudden change in illumination, such as a shadow, can be detected by nereids but could be caused by a predator, by food, such as floating seaweed and, innocuously, by a passing cloud. Even if the necessary mechanisms existed, conditioning would be difficult to establish in this situation and would be of doubtful value to the animal. This is because in nature conditioned stimuli probably occur at random with different kinds of reinforcing events.

I thank Prof. R. B. Clark and Prof. J. Z. Young, who both criticized the original manuscript.

ASTRONOMY

Evidence on the Evolutionary Character of the Universe derived from Recent Red-shift Measurements

Hoyle and Burbidge[1] have recently examined the red-shifts of a number of quasi-stellar radio sources[2,3] and have plotted their radio flux densities (S) against red-shift (z); they conclude that the results are inconsistent with a cosmological interpretation of these red-shifts.

This communication shows that this conclusion is not valid and that indeed the observed relationship between S and z provides valuable new information on the evolutionary nature of the Universe.

There is now considerable evidence in favour of evolutionary cosmologies, the most important observations being (*a*) the counts of radio sources[4,5], (*b*) the detection of cosmic radiation with a black-body spectrum[6-9], and (*c*) the present abundance of cosmic helium[10,11]. The possibility that quasi-stellar sources are of relatively local origin is now difficult to accept in view of (*a*) the isotropy of the counts of faint radio sources over the northern sky[12,13], (*b*) the absence of quasi-stellar sources showing blue-shifted spectral lines[14] and (*c*) the marked similarity between the radio properties of a number of quasi-stellar source counts has been considered by Davidson and *MSH* 14-1-21 (ref. 16) and 3*C* 245 (ref. 17) all appear optically to be quasi-stellar sources and yet have a radio structure very similar to radio galaxies such as Cygnus *A* and 3*C* 33.

The nature of the evolutionary changes in the properties of radio galaxies which are necessary to explain the radio source counts has been considered by Davidson and Davies[18] and more recently by myself[19]. In the second article, it was shown that changes with epoch of either the mean spatial density (density evolution) or the mean luminosity (luminosity evolution) of powerful extra-galactic radio sources could explain the excess of faint sources in the log N − log S relationship. It has been suggested that quasi-stellar sources may account for a large part of this excess since it has been shown that the slope of the source counts for such sources is steeper than that of the total source counts[19,20].

In cosmologies involving density evolution, the sources at all distances have the same distribution of radio luminosity, P, and the plot of S against z will follow the usual relationship:

$$S = \frac{P}{r^2(1+z)^{1+\alpha}}$$

where α is the spectral index ($S \propto \nu^{-\alpha}$) and r the distance of the radio source which is given by

$$r = \frac{2c}{H}(1-(1+z)^{-\frac{1}{2}})$$

in the Einstein-de Sitter world model. Because more than 80 per cent of the local quasi-stellar radio sources ($z < 0{\cdot}5$) have luminosities in the range $4 \times 10^{25} < P_{178} < 6 \times 10^{26}$ W(c/s)$^{-1}$ ster.$^{-1}$, it is possible to draw on the $S-z$ diagram the limits within which most of the quasi-stellar radio sources should lie.

If, on the other hand, the excess of faint sources is attributed to luminosity evolution, the $S-z$ relationship must be modified to take account of the increased luminosity of sources at earlier epochs. As Longair[19] has shown, the luminosity evolution required may be defined by $\bar{P} \propto t^{-x}$ where $x \sim 2$. ($\bar{P}$ is the mean luminosity at epoch t.) Lines on the $S-z$ diagram corresponding to the limiting values of P_{178} at the present epoch may again be drawn. The results of these calculations for the two types of evolution are shown in Fig. 1 superimposed on the distribution of points presented by Hoyle and Burbidge restricted to sources for which $S_{178} \geqslant 8 \times 10^{-26}$ W m^{-2}(c/s)$^{-1}$. (Only at values greater than this flux density have complete searches for quasi-stellar sources been carried out and of those found, roughly 50 per cent have measured red-shifts.)

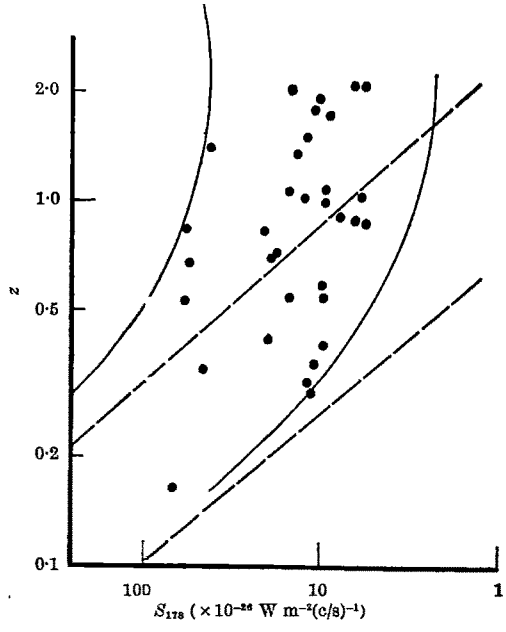

Fig. 1. The red-shift flux density plots expected in evolutionary cosmologies in which density evolution (dashed lines) and luminosity evolution (full lines) are included. The distribution of observational points is that presented by Hoyle and Burbidge restricted to $S_{178} \geqslant 8 \times 10^{-26}$ W m^{-2}(c/s)$^{-1}$.

It can be seen from Fig. 1 that cosmologies involving luminosity evolution can explain entirely the wide dispersion of points in the $S-z$ plot whereas, in those involving density evolution, only 45 per cent of the quasi-stellar sources lie within the expected limits. In the latter type of evolutionary cosmological model, it is difficult to account for those sources lying appreciably above the upper limit.

These results suggest that the observed log $N-\log S$ relationship arises from the increased luminosity of powerful radio sources at early epochs. Such a variation of luminosity with epoch implies that sources at a given flux density should include a wide range of red-shifts and this provides a natural explanation for the presence of distant quasi-stellar sources even at high flux densities

(for example, $3C298 : z = 1{\cdot}436$, $S_{178} = 44 \times 10^{-26}$ W $m^{-2}(c/s)^{-1}$).

An Apparent Increase in Galactic Radio Noise during a Total Solar Eclipse

DURING the total eclipse of 1965, May 30, observations were made on the island of Manuae (lat., 19° 15′ 43″ S.; long., 158° 57′ 43″ W.) of changes in the *D* layer absorption of radio signals, and also of fluctuations in the galactic noise level at 18·2 Mc/s. The latter observations in particular produced an unexpected effect which is reported here.

The apparatus used in measuring the noise consisted of two half-wave dipoles in phase, with reflectors, the main lobe being directed at R.A. 1h 20m, Dec. 16° 21′ S., that is 8° from the zenith in a direction W. 20° S. This aerial fed a low noise receiver of 10 kc/s bandwidth, and the audio-output was amplified, rectified and used to drive a pen recorder. The system was calibrated with a 5722 noise diode.

Observations were made between 18h 45m and 21h 00m U.T. on every day between May 27 and June 2. Time markers were received from station *WWVH* and placed manually on the chart.

The unexpected feature consisted of two large bursts of noise, each of 13 sec duration, the leading edges of which coincided to 3 sec with the times of optical second and third contacts. The mean power level in each burst was about 2·5 times the mean noise power during the eclipse. No such similar bursts occurred at any other time while observations were being made. Because all expeditions on the Island had collaborated in the detection, identification and elimination of any sources of local radio interference, we are satisfied that the noise originated from a source outside the island.

Reduction of the data on this and other observations is not yet complete.

PLANETARY SCIENCE

A Method for Translunar Radio Communication

THE increase of human activity on the lunar surface that can be expected to follow the first manned landings will present a special problem in translunar communications. The lack of an ionosphere about the Moon, the lack of any appreciable atmosphere on the lunar surface, and the nearness of the lunar horizon, require solutions to this problem that may be somewhat different from those most easily available on the Earth's surface. Extended radio coverage about the lithosphere, such as occurs on Earth because of the atmospheric density gradient and temperature inversions, will not be possible because of the vanishingly low density of any gaseous envelope that may exist around the Moon.

Consideration of the special properties which are believed to be likely for the lunar lithosphere[1,2] indicates a possible solution: that the sub-lunar surface materials can be used as a propagation medium for translunar communication.

The immediate surface layers have an extremely low thermal conductivity and a very low content of liquid water, as shown by microwave thermal observations. Thus there is some evidence that the outer layers of the Moon contain considerable quantities of material similar to earthly pumice, in that this material has been expanded by gas bubbles during some stage of formation, and/or was formed from meteoric splash dust and thermal cycle spallation products, re-welded on succeeding surfaces by direct solar action.

The depth to which these conditions exist is of course at the moment a matter of pure speculation. However, if they persist for an appreciable depth, then a considerable volume of the outer part of the Moon is likely to be transparent to radio waves in the range from the lowest frequencies that can be radiated by practical antennae up to frequencies in the tens of megacycles per second. The depth of this transparency is probably a function of radio frequency, because microwave thermal observations[3] show some transparency even for microwaves in a thin layer of the outer surface.

Antennae placed on the surface of the Moon should give coupling to sub-surface waves with which astronauts can communicate beyond the lunar horizon. Trailing wire antennae can be simple and inexpensive as compared with arrays of microwave dish antennae, which have the additional disadvantage of being confined to line-of-sight use.

The advantages of sub-lunar low frequency communications seem obvious. Very compact receivers of low mass and transmitters of great reliability are available from simple designs using solid-state active elements and microcircuitry type construction. The principal problem is the primary power. Storage cells and solar cells in combination have already shown their adaptability in the lunar surface environment, in connexion with the *Surveyor* soft landing and picture transmission.

The remaining problem is that of determining the true nature and extent of the outer portion of the Moon in respect to its radio transmission properties. If the outer layers are sufficiently transparent to a suitable radio frequency, the internal reflexion from the lunar surface and the ray curvature resulting from increased density as a function of depth should ensure a strong wave component along and just below the surface, with sufficient evanescent wave penetration through the surface to ensure antenna coupling.

The foregoing possibilities make it very desirable to obtain measurements of lunar sub-surface properties in relation to radio transparency and the depth of the transparent layers, before the arrival of manned landing parties. This information should be obtainable by means

of a suitable circumlunar transmitting or receiving satellite. Which of these approaches is most economical depends on a detailed assessment of ionosphere penetration of signals at the Earth terminal and of the effect of Earth atmospherics.

Because this evaluation will be long and involved, the results that can be expected from a basic satellite transmitter system will be outlined here as an example from which we can judge the information that is possible from this type of experiment. Reflected wave-lengths of metre size and greater indicate a smooth figure for the lunar surface as a whole[4]. The portion of the Moon which is transparent to radio waves should act as a spherical lens and therefore as a gigantic focusing antenna. If the index of refraction of the transparent lunar material for radio waves lies between 1·25 and 2, as is true for light terrestrial rocks, then a satellite orbiting at a distance of between 300 miles and 50 miles above the lunar surface will produce a strongly focused beam from the Moon, which acts as a lens antenna. As the transmitting satellite passes behind the Moon from the Earth, this beam should pass across the surface of the Earth.

The strength of the central lobe of this beam will depend on the transmitter power and radiator gain, and on the degree of transparency and area of this lunar material. The angular size will depend on the relation between the satellite position and the ideal focal point of the Moon as a lens, as well as the relation between the lunar diameter and the wave-length. The relative angular size and phase of the side-lobe pattern will depend on the radial depth of the transparent layer and the transmitted frequency. Several passes, each transmitting a different frequency, or a time-sharing system between pulses of various frequencies to obtain data from several frequencies at a single pass, should produce data equivalent to an imagined X-raying of the Moon. Thus a small unmanned lunar satellite could be used as a vehicle to determine the feasibility of a miniature and simple system of translunar voice communication, and at the same time could considerably increase our knowledge of the internal structure of the Moon. The cost of this effort would be quite small compared with the cost of a manned landing, and could contribute considerably to the safety and comfort of future lunar explorers.

Occurrence of Hydrogen Peroxide in Sea Water

TRACES of dissolved substances, of the order of 10^{-7} M or less, can or may have far-reaching effects on the type or growth rate of organisms in the sea[1]. We now wish to report the occurrence of a possible ectocrine, hydrogen peroxide, in surface sea water samples taken near Port Aransas. We have no direct evidence suggesting that hydrogen peroxide in sea water has any biological or chemical significance; however, from continuing experiments on the growth of single cells of coccoid blue-green algae on agar plates[2,3], we are led to propose that it could be a significant ecological variable.

Hydrogen peroxide was measured in sea water samples using the sensitive scopoletin-peroxidase fluorescence technique of Andreae[4] and Perschke and Broda[5]. For the values reported here a stoichiometry of one part scopoletin to one part hydrogen peroxide was used. Changes in fluorescence were detected with a barrier cell (*IRC A-10M*) and measured on a Keithley model 150*A* microvolt–ammeter. (An American Instrument Co. photomultiplier microphotometer was used in later work.)

Table 1. HYDROGEN PEROXIDE IN SURFACE SEA WATER SAMPLES

Location	μg hydrogen peroxide/l.
Boat basin adjacent to Institute	1 6, 1·6, 2·8
Tide pool near beach	0 5, 6 7, 2 6
Beach near South Jetty	5 8, 1 0, 4·0
Open Gulf	5·5, 3·3

For the first three samples: Date and weather conditions shown in order left to right: April 21, mostly cloudy, air temp. 27° C; June 3, bright sun, air temp. 31° C, south-easterly wind at 15–20 m.p.h.; July 8, bright sun, air temp 31° C, south-easterly wind at 20–22 m.p.h. Open Gulf samples: first sample June 11, 10 miles offshore, blue water, clear sky, south-easterly wind at 5–10 m.p.h.; second sample September 14, 5 miles offshore, turbid water, clear sky, south-easterly wind at 12–15 m.p.h.

The sea water samples were collected in 'Pyrex' or plastic containers. They were assayed as soon as possible, usually within 30 min. A typical assay consisted of the following: 6 ml. of sea water (unfiltered); 0·5 ml. (1 μg) of scopoletin (Mann Laboratories); and 0·5 ml. of 0·08 M *tris* buffer, *p*H 8·0. The initial fluorescence baseline was measured, then 0·05 ml. (200 μg) peroxidase, Sigma Chemical Co., Type II, was added. The addition of catalase to samples of sea water which gave strongly positive assays of hydrogen peroxide resulted in complete loss of activity in the scopoletin-peroxidase system.

Table 1 shows some of the results found. Our experience so far would suggest that the presence of traces of hydrogen peroxide is a constant feature of sea water taken from the Port Aransas area.

We make no specification as to the source of the hydrogen peroxide. It could be formed photochemically in the atmosphere, photochemically in sea water itself through catalysis by dissolved pigments[6] or possibly even through the metabolic activity of micro-organisms. The data so far do not allow a choice to be made from these possibilities. This work was supported by the National Science Foundation.

Surface Tension of Slick Patches near Kelp Beds

DURING a voyage off southern California near Santa Catalina Island some surface tension measurements were made on the open sea and over and around the slick areas associated with kelp beds. The usual methods of measuring surface tension involve laboratory equipment which is not feasible for use aboard a small sailing ship. For this reason, these tests were made with drops of a series of ten oil solutions, calibrated so that each solution would just spread against a different specific surface pressure, or lowering of surface tension. This calibrated series made it possible to measure, by inspection, surface tensions in the range 76–30 dynes/cm.

Based on N. K. Adam's[1] technique, a series of solutions of a hydrophilic compound, *n*-dodecyl alcohol, and non-spreading oils was standardized so that a drop of each oil solution just spread against a measured surface tension. Solutions of known surface tensions, determined by a Du Nuoy tensiometer calibrated with distilled water, were

made with potassium chloride, a surface-active agent known as 'Aerosol *OT*', and distilled water, as listed in Table 1. 'Aerosol *OT*' is a waxy solid form of sodium dioctyl sulphosuccinate produced by the American Cyanamid Co. The quantities of 'Aerosol *OT*' used varied from 0 to 0·1 per cent by weight, and the oils used were Sargent's light mineral oil (80°–90° Saybolt, 35 dynes/cm surface tension) and *n*-decane (Eastman Organic Chemicals *P* 2405). The amounts of *n*-dodecyl alcohol (Eastman 873) in the spreading oils varied from a trace in the 76 dynes/cm solution to 0·18 per cent by volume in the 30 dynes/cm solution. The small amounts of *n*-dodecyl alcohol were added in the form of a 10 per cent solution of the alcohol in *n*-decane.

Table 1. COMPOSITION OF CALIBRATED SURFACE TENSION OILS

Surface tension (dynes/cm)	Standardizing solutions	Spreading oil base
76	Potassium chloride (14 wt. per cent)	Mineral
74	Potassium chloride (6 8 wt. per cent)	Mineral
72	Distilled water	Mineral
70	'Aerosol *OT*'	Mineral
68	'Aerosol *OT*'	Mineral
61	'Aerosol *OT*'	Mineral
58	'Aerosol *OT*'	Mineral
50	'Aerosol *OT*'	20 per cent decane in mineral
40	'Aerosol *OT*'	*n*-decane
30	'Aerosol *OT*'	*n*-decane

A sample of open sea surface water taken from near the mid-point of the Outer Santa Barbara Channel was stored in an overflowing plastic container. Its surface tension was measured 6 days later with a Du Nuoy tensiometer. We found a value of 74 dynes/cm, which agrees with that expected for open sea water. This value can be used as a standard of comparison for the surface tension values measured on the slick patches. All other measurements were made by direct application of the oil drops to the sea surface.

Sieburth and Conover[2] reported decreases of 1–3 dynes/cm in the surface tension of natural slicks in the Sargasso Sea, compared with non-slick areas nearby. They considered that the slick areas were formed by the ripple damping action of monomolecular layers of organic matter produced by blue-green algae *Trichodesmium erythraeum*. The present report deals with the slick patches associated with the kelp beds near the shore of Santa Catalina Island. The predominant kelp of these beds is *Macrocystis pyrifera*[3], commonly called "Devil's Apron".

The areas of testing were two coves, Howland's and Moonstone Beach, on the north-east side of Santa Catalina, each of which had a fairly sheltered harbour and slick kelp patches near the shore. When measurements were made, our boat was the only one in the harbour and the oil drops were applied from a small skiff drifting over the areas.

In both coves the surface tension of the open rippled water measured consistently between 70 and 72 dynes/cm. Landward, the surface tensions varied from 68 to 70 dynes/cm at the outer edge of the slick areas to 58 and 61 dynes/cm directly over the kelp plants.

At Moonstone Beach it was possible to make surface tension measurements along a line extending from the clear water in the harbour, across a large kelp bed slick, to the shore, with a strong 8–10 m per sec on-shore wind blowing. The values of surface tension in the clear water upwind of the slick were 70 dynes/cm; on the very edge of the slick, 61 dynes/cm; over the kelp, 58; downwind towards shore, 50; and still closer to shore, less than 50 but more than 40 dynes/cm. In the backwash from a small tidal cave the surface tension measured 58 dynes/cm.

These values suggest that the metabolic processes of the kelp produce organic material which lowers the surface tension of sea water. The organic material from the kelp evidently stays concentrated near the surface, for in the backwash of a tidal cave the decrease in surface tension was less than in the surrounding area, owing to the admixture of under-surface water.

We thank Dr. Alexander Goetz for making possible the trip on his boat.

Occurrence of Permafrost at an Arctic Lake

A FIELD investigation was carried out in April 1961 to determine the distribution of permafrost below a lake in the Mackenzie River delta[1–3]. This study was of special interest inasmuch as the delta lake is situated in an old river bed and the occurrence of permafrost is considerably affected by the large number of lakes and channels in the immediate vicinity. A similar but more detailed investigation was undertaken by the Division of Building Research of the National Research Council of Canada during April and May 1964 at a small lake about 5 miles north-east of Inuvik, Northwest Territories. This lake was selected because it was completely isolated from other bodies of water which might influence the ground thermal regime.

The lake is located on the edge of the rolling upland which forms the eastern boundary of the Mackenzie delta. It is about 1·25 miles from the delta at an elevation about 340 ft. above the delta, and is nearly rectangular in shape (about 800 ft. long by 400 ft. wide) with a maximum depth of 19 ft. No streams flow into the lake.

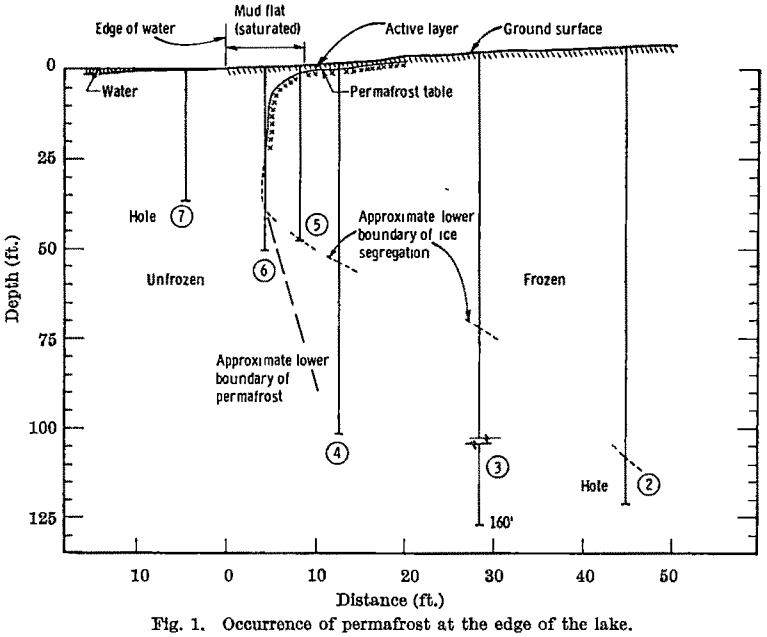

Fig. 1. Occurrence of permafrost at the edge of the lake.

It is replenished by snow melt water from its very small drainage basin. A small stream issues from the south-west end and drains to the delta. The lake is situated in the transition zone between the tundra to the east and the forested delta to the west. Although stunted white spruce are scattered over the area, the predominant vegetation consists of willow and alder and low brush. *Sphagnum* and other mosses with patches of lichen form the ground cover. The entire area surrounding the lake is covered with large hummocks up to 2 ft. high and 7 ft. in diameter. The mean annual air temperature at Inuvik is about 14° F. Permafrost is continuous below the ground surface and is hundreds of feet thick.

The main intention of the field programme was to determine the distribution of permafrost near the edge of the lake and to provide instrumentation which would enable an analysis to be made of the ground thermal regime below and adjacent to the lake. The investigation consisted of drilling and sampling nine holes at or adjacent to the east edge of the lake. Good cores were recovered of most of the frozen materials encountered.

Hole No. 1 (312 ft. deep) was situated on the top of a ridge about 850 ft. from and 50 ft. higher than the lake. Hole No. 9 was drilled to a depth of 320 ft. below the lake (in 12 ft. of water) about 60 ft. from shore. The remaining seven holes were drilled to depths of 40–160 ft.; five of them were on the shore and two in the lake (Fig. 1). A number of hand probings were also made between these holes to determine the maximum seasonal frost penetration (May) and depth of thaw (September). Thermocouple cables were installed to depths of 50–300 ft. to measure ground temperatures in five of the holes. In addition, three specially designed and fabricated temperature recorders (which will run unattended for at least one year) were installed. Surveys were also made to map lake bottom and ground surface contours.

From 2–35 ft. of organic silt overlies 100–150 ft. of dense stony till. The till is underlain by a thinly stratified shale. The depth to which ice segregation was noted increased with distance from the edge of the lake. The lowest depths at which ice segregation was observed in the holes at the edge of the lake are indicated in Fig. 1. No frozen ground was encountered in the three holes below the lake. At hole No. 6 (5 ft. from the edge of the lake), permafrost occurred from about 24 ft. to 40 ft. Initial ground temperature observations indicate a thickness of permafrost of about 250 ft. in hole No. 3, which was about 28 ft. from the edge. Frozen ground exists for the full depth of hole No. 1 and a thickness of more than 400 ft. is indicated by the ground temperatures. Ice segregation was observed to a depth of about 290 ft. in this hole. The drilling operation considerably disturbed the ground thermal regime in the boreholes and thermal equilibrium has not yet been restored. Measurements are at present being made to determine the mean lake bottom temperature, the mean ground surface temperature and the geothermal gradient.

It is possible to draw some general conclusions from the initial field observations. It is probable that the size and shape of the lake have remained unchanged for a long period of time. Little variation in water level and a very slow accumulation of bottom sediment would be expected because the lake is replenished only by local snow melt each year, and no sign of large-scale erosion or slumping has been observed on the perimeter of the lake. The small stream draining the lake would provide a natural control on the water level.

The effect of this very small water body on the occurrence of permafrost is quite pronounced. The existence of a deep thawed zone below the lake is a direct result. It is probable that permafrost is completely absent below the lake. Although the thawing effect of the water is confined to the ground lying beneath the lake, as shown by the presence of permafrost at the shoreline, the initial ground temperature measurements indicate that the thermal effect of the lake extends for some distance beyond its perimeter.

Some Seismological Features of the North Macquarie Ridge

THE recent demonstration of the existence of a ridge connexion between Macquarie Island and New Zealand, by Brodie and Dawson[1], has clarified several aspects of the regional seismology. Fig. 1 relates epicentres determined during the past 5 years by the United States Coast and Geodetic Survey in the area, to the bathymetry as presented by Brodie and Dawson. Seismicity is seen to be definitely associated with the ridge structure. There is one case (about 55° S., 163° E.) notably distant from the

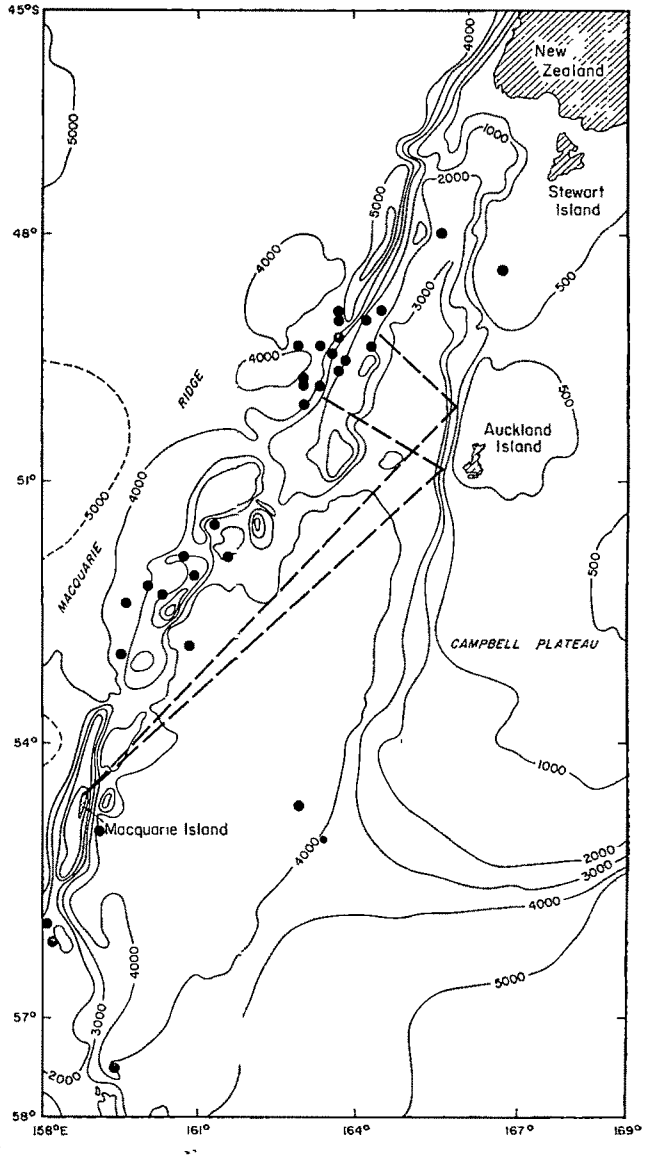

Fig. 1. Depths in metres.

ridge; from consideration of P phase arrivals at Australian stations, this is believed to be a mislocated ridge shock. Thus the Campbell Plateau appears to be aseismic, at least during this period. The marked offset in the ridge at about 51° S., noted by Brodie and Dawson, could suggest a fracture zone similar to those reported along the equatorial part of the mid-Atlantic ridge by Heezen *et al.*[2]. However, no epicentres have been located near this feature during the period considered.

The Bureau of Mineral Resources has operated a seismological station at Macquarie Island since 1951. A puzzling feature of Macquarie Island records of shocks in the group north-west of Auckland Islands has been a frequent anomalously late T phase arrival. These arrivals had been provisionally interpreted as T waves reflected at the edge of the Campbell Plateau. The new bathymetric map makes this interpretation entirely feasible. Typical paths for such reflected T phases are shown in Fig. 1.

Material on the T phase as recorded at Macquarie Island is being prepared for publication. This will include more detail concerning these reflexions.

P Amplitudes from *Longshot* at Australian Stations

THE P phase from the nuclear explosion *Longshot*, detonated beneath Amchitka Island at a depth of 2,300 ft. on October 29, 1965, was well recorded at most Australian seismograph stations. The amplitudes of ground displacement at these stations have been plotted against distance in Fig. 1. These amplitudes were calculated from the peak-to-peak amplitude of the first cycle of P motion on each record. U.S. Coastal and Geodetic Survey station abbreviations have been used in the figure, with the addition of the recently established Warramunga array at Tennant Creek (TCA), and the South Australian station at Cleve (CLV). Details of the stations have been given by Doyle and Underwood[1].

Despite the scatter common to all amplitude studies, the data clearly show a sharp decrease in amplitude between 92° and 93°. It is unlikely that this marks the shadow boundary of the core, especially as studies of PcP from nuclear explosions[3-4] indicate that the depth of the core-mantle boundary is not far from that calculated by Jeffreys[5]. It is more probable that the effect is due to the influence of the D'' layer[6]. A recent study of travel times by Cleary and Hales[7] suggests that $dT/d\Delta$ is approximately constant from about 93°. A condition

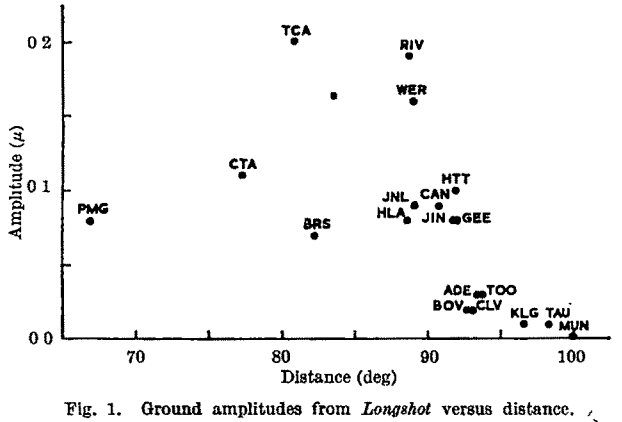

Fig. 1. Ground amplitudes from *Longshot* versus distance.

approaching this would account for the decrease in amplitude.

At Cleve and Adelaide, the small P amplitudes disclose a larger impulsive arrival about 1 sec later. This is too late to be pP, and any arrival which had travelled along the path of the initial P would be similarly diminished in amplitude. The phase is therefore most readily interpreted as PcP, providing further evidence that the bottom of the P ray path is above the core-mantle boundary for this distance.

The period of P decreases from 1·1 sec to 0·8 sec as the distance increases within the range, but the decrease appears to be fairly uniform and unrelated to the amplitude change. This phenomenon, together with travel time observations, will be discussed in detail elsewhere.

I thank the directors of the Bureau of Mineral Resources, the Geophysics Departments of the Universities of Brisbane, Adelaide and Hobart, and Riverview Observatory, for making records available. R. Underwood supplied seismograph calibrations for all stations operated by the Australian National University.

A Model for the Occurrence of Large Earthquakes

THIS communication outlines a probability model which seems to provide an adequate basis for making predictions concerning the occurrence of largest earthquake magnitudes over time: (*a*) The number of earthquakes in a year is a Poisson random variable with mean α; (*b*) X, the earthquake magnitude, is a random variable distributed with cumulative distribution function:

$$F(x) = Pr\,(X \leqslant x) = 1 - e^{-\beta x},\ x \geqslant 0 \qquad (1)$$

From these assumptions it follows that Y, the largest annual earthquake magnitude, is distributed with cumulative distribution function $G(y)$, where

$$G(y) = Pr\,(Y \leqslant y) = \sum_{k=0}^{\infty} \frac{e^{-\alpha}\,\alpha^k}{k!} \left[F(y)\right]^k$$

$$= \exp\left\{-\alpha\left[1-F(y)\right]\right\} = \exp\left(-\alpha e^{-\beta y}\right),\ y \geqslant 0 \qquad (2)$$

The cumulative distribution function (2) is called the "type 1" distribution of largest values in the terminology of Gumbel[1].

In order to estimate the parameters α and β from $y_1, y_2, \ldots, y_n$, the largest annual earthquake magnitudes in n years, one arranges these values in order of increasing size $y_{(1)} \leqslant y_{(2)} \leqslant \ldots \leqslant y_{(n)}$, where $y_{(j)}$ is the jth smallest annual maximum magnitude. To each $y_{(j)}$, one associates the value $G(y_{(j)}) = j/(n+1)$. The parameters α and β are found from the least-square fit to the equation

$$\log\left[-\log G(y)\right] = \log \alpha - \beta y \qquad (3)$$

derived from equation (2).

It should be noted that $\alpha e^{-\beta y}$ is the expected number of earthquakes, N_y, in a given year which have magnitude exceeding y. It follows that

$$\log N_y = \log \alpha - \beta y \qquad (4)$$

which is of the same form as the widely used empirical formula

$$\log_{10} N_y = a - by \tag{5}$$

(see, for example, ref. 2). The parameters a and b are related to α and β as follows:

$$a = \log \alpha / \log 10 \qquad b = \beta / \log 10 \tag{6}$$

The parameter β also has a physical meaning, since $1/\beta$ is the mean magnitude of all earthquakes of magnitude $x > 0$. If X_0 is the magnitude threshold of the observations, then $X_0 + 1/\beta$ is the mean magnitude over the data range used.

In addition to relation 4, several other useful ones can be obtained from the model. It is, for example, an immediate consequence of the model that T_y, the mean return period (that is, the mean interval in years) between earthquakes having magnitude greater than y is given by

$$T_y = 1/N_y = \exp(\beta y)/\alpha \tag{7}$$

Another quantity of interest is $\tilde{y}$, the modal (most probable or most frequently observed) annual maximum magnitude. Since $\tilde{y}$ is the value for which $g(y) = G'(y)$ becomes maximum, it can be shown that

$$\tilde{y} = \frac{\log \alpha}{\beta} \tag{8}$$

It is readily verified that $N\tilde{y} = 1$, that is, $\tilde{y}$, is the magnitude such that we can expect one earthquake having magnitude $\tilde{y}$ or more in a given year (another way of saying this is that the mean return period of $\tilde{y}$ is $T_{\tilde{y}} = 1$). Also, $G(\tilde{y}) = e^{-1}$; that is, $\tilde{y}$ is that maximum annual magnitude which is exceeded in the long run 63 per cent of the time.

The modal earthquake magnitude in a T year period is

$$\tilde{y}_T = \log(\alpha T)/\beta = \tilde{y} + \frac{\log T}{\beta} \tag{9}$$

The value y_p of the maximum annual earthquake magnitude which is exceeded with probability p is found by solving the equation

$$\exp(-\alpha e^{-\beta y_p}) = 1 - p \tag{10}$$

which yields

$$y_p = \tilde{y} - \frac{\log[-\log(1-p)]}{\beta} \tag{11}$$

More generally, $y_p(D)$, the value of the maximum earthquake magnitude which is exceeded with probability p in a D year period, is given by

$$y_p(D) = y_p + \frac{\log D}{\beta} \tag{12}$$

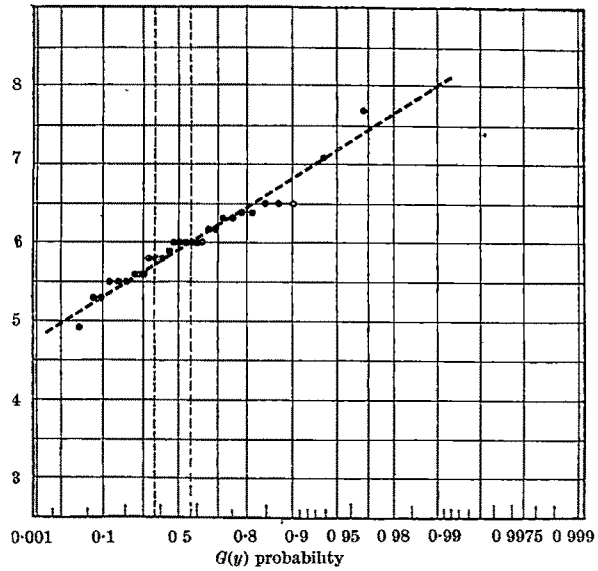

Fig. 1.

Finally, the earthquake risk $R_D(y)$ (ref. 3), that is, the probability of occurrence of an earthquake of magnitude y or more in a D year period, can be written as

$$R_D(y) = 1 - \exp(-\alpha D\, e^{-\beta y}) \tag{13}$$

Calculations based on this model have been carried out for earthquakes in California for the period 1932–62. Table 1 lists the magnitude maxima by increasing size.

Table 1. CALIFORNIA YEARLY EARTHQUAKE MAXIMA (1932–62) BY ORDER OF INCREASING SIZE

j	$y(j)$	$G[y(j)]$
1	4·9	0·03125
2	5 3	0 06250
3	5 3	0 09375
4	5·5	0 12500
5	5·5	0 15625
6	5 5	0 18750
7	5·5	0 21875
8	5·6	0 25000
9	5 6	0 28125
10	5 6	0·31250
11	5 8	0 34375
12	5·8	0 37500
13	5·8	0·40625
14	5·9	0 43750
15	6·0	0·46875
16	6·0	0 50000
17	6·0	0 53125
18	6·0	0·56250
19	6 0	0·59375
20	6 0	0 62500
21	6·2	0·65625
22	6 2	0 68750
23	6 3	0 71875
24	6 3	0 75000
25	6 4	0 78125
26	6·4	0·81250
27	6·5	0 84375
28	6·5	0 87500
29	6 5	0 90625
30	7 1	0·93750
31	7·7	0·96875

The values given in Table 1, plotted on extremal probability paper (ref. 1), yield an acceptable straight line fit, as shown in Fig. 1. From this graph it is possible to determine approximate values for the parameters α and β of the distribution $G(y)$ of annual extreme earthquakes in California. More accurately, the data given in Table 1 can be fitted to equation (3) by a least-square regression procedure such as *REGRESS*, a computer routine available within the *STATPAK* statistical system at the University of California[4]. Application of this procedure to the data in Table 1 yields 11·43 and 2·00 as estimates, respectively, of $\log \alpha$ and β. The standard deviation of β was estimated as 0·08 by the same programme.

Gutenberg and Richter[5] give $0{\cdot}88 \pm 0{\cdot}03$ as an estimate of their parameter b for Southern California, which yields (see equation 6)

$$\beta = 2{\cdot}03 \pm 0{\cdot}07$$

which gives reasonable agreement with our estimate derived from only thirty-one annual maxima. Our predicted modal annual maximum (equation 8) is:

$$\tilde{y} = 11{\cdot}43/2{\cdot}00 = 5{\cdot}715$$

In view of the fact that the modal value $\tilde{y}$ is exceeded 63 per cent of all years we have $G(\tilde{y}) = 0{\cdot}37$, which corresponds to a magnitude $\tilde{y} = 5{\cdot}8$ in Table 1. Again, the agreement is excellent.

Let us now compute N_y, the expected number of earthquakes per year, and T_y, the mean return period, for shocks of magnitude greater than or equal to y in California. Using equations (4) and (7) with the values of α and β already obtained we find the estimates given in Table 2.

Table 2. PREDICTED YEARLY NUMBERS AND RETURN PERIODS FOR CALIFORNIA EARTHQUAKES

Magnitude y	Yearly expected number N_y	Mean return period T_y
3	228	1·6 days
4	20 7	17·6 days
5	4 18	87·3 days
6	0·57	1·8 years
7	0 076	13·2 years
8	0 010	100·0 years
9	0 0014	720 years

The model presented in this note should be considered as a first approximation to the real situation. In an area as large and complex as California there is considerable geographical variation both as to frequency and magnitude of occurrence of earthquakes. A more refined model would be obtained by dividing the area into two or more regions and fitting the seismicity in each of these regions by the model. However, despite the known lack of homogeneity of earthquake occurrence in California the present simplified approach provides reasonable estimates for the occurrence of large earthquakes within the uncertainty due to the shortness of the available historical record.

PHYSICS

The Temperature Scale

THE temperature scale recently proposed by Georgian[1] has stimulated us to spend some time considering both the temperature scale and the dimensions to be associated with temperature. We shall begin by outlining details of various temperature scales which have been suggested during the past hundred years:

Rucker, 1889[2]. Let one degree be the temperature increase required to add one erg of energy to 1 c.c. of air at 0° C and one atmosphere. Rücker made his suggestion *exempli gratia*, saying that ". . . our knowledge of the molecular construction and dynamics of solids and liquids is as yet too imperfect to warrant an attempt to place thermal units on a natural and mechanical basis".

Planck, 1912[3]. $k = 1$—the degree is defined by setting Boltzmann's constant equal to unity. This was part of a system of "natural units" in which the units for mass, length, and time were defined by setting the velocity of light, the gravitational constant, and Planck's constant equal to unity.

Lewis and Adams, 1914[4]. $k = 1$ defines the degree, as with Planck. This was part of a system of "ultimate rational units" in which the velocity of light, the charge on the electron, and the mass of the electron were made equal to unity. Lewis and Adams also considered the possibility of $R = 1$ (universal gas constant per mole), but preferred $k = 1$.

McAdie, 1917[5]. Melting ice at 1,000 kilobars is defined as 1,000° N (for New), with zero at absolute zero This scale was selected as convenient for meteorological data.

Worthing, 1940[6]. Discusses several possibilities and rejects them all.

Brown, 1942[7]. The temperature of a system is defined as the specific pressure-volume energy (in ergs/g) of hydrogen in thermal equilibrium with the system. With all measurements thus referred to a specific thermometric gas, temperature can be considered proportional to the mean square velocity of the molecules of this particular gas, and its dimensions can be taken as L^2T^{-2}.

Laws, 1962[8]. Let one degree be the temperature increase required to add one joule of energy to 1 g of water.

Georgian, 1964[1]. $R = 1$, in conjunction with the metre–kilogram–second (M.K.S.) system.

Overcoming our reluctance to add to a list which may already be too long, we now suggest that the degree be defined so that $R = 2$ (M.K.S. basis). In an ideal gas:

$$E = \frac{3}{2}R\theta \qquad (1)$$

where E is the internal energy per mole and θ is the absolute temperature. Since each molecule has three (translational) degrees of freedom, we choose $R = 2$, thereby making temperature the molal internal energy per molecular degree of freedom:

$$\theta = \frac{E}{3} \qquad (2)$$

We would express temperature in the M.K.S. system, (joules/kg mole)/(degrees of freedom/molecule) and, like Georgian, scale it up by 10^4 for convenience.

In a broad sense, the temperature thus defined is the molal internal energy per degree of freedom for any substance, because at thermal equilibrium the same quantity of energy is stored by each fully activated degree of freedom. Degrees of freedom other than translational are quantized, and will be only partly activated at low temperatures. This does not, however, destroy the utility of the concept of energy per degree of freedom. A well known application is the calculation of heat capacity from spectral data, which involves estimating the extent to which various degrees of freedom are activated.

Our view of the dimensions of temperature differs from that of Georgian. From equation (2) we assign temperature the same dimensions as E, and we consider that E has dimensions ML^2T^{-2}. Since E is energy per mole, we are thereby saying that n, the number of moles, is a dimensionless number. The problem of the dimensions of n has been discussed in detail by Duncanson[9]. Briefly, we think of the number of moles as being analogous to the number of molecules. A mole can be defined as a specified number of molecules, and for many purposes a mole can be treated as a macromolecule.

It is possible to give temperature the dimensions L^2T^{-2} by following the procedure of Brown[7]. Georgian seems to take this view, because in putting forward an argument in favour of these dimensions on the basis of the kinetic theory, he says[10]: " . . . the temperature is directly proportional to the mean square velocity of the molecules in an ideal gas". This can be so only if, like Brown, he considers a single specified gas, with a particular molecular weight, as a unique thermometric substance to which all measurements are referred. Otherwise two ideal gases of different molecular weights in thermal equilibrium would not have the same temperature, because their molecular velocities would be different.

On the other hand, if we say that temperature is proportional to the mean kinetic energy of the molecules, then all ideal gases of all molecular weights can serve equally well as thermometric substances.

The relative merits of ML^2T^{-2} and L^2T^{-2} as dimensions for temperature are discussed in more detail by Focken[11]. We find the arguments of Focken and of Duncanson[9,12] more convincing than those of Porter[13], cited by Georgian[14].

Finally, we would like to comment on Georgian's statement that henceforth "In using temperature in dimensional analysis we will not fall into the error of considering temperature endowed with a separate dimension". We believe that many problems in dimensional

analysis can be formulated with a separate dimension for temperature with no consequent error in the solution[15].

Fine Structure in the Radial Distribution Function from a Random Packing of Spheres

EARLIER, we reported[1] the radial distribution function from a random packing of spheres covering the range of sphere separations from 1·0 to 1·3 diameters. Inspection of the data indicated some possible fine structure in the distribution function. The results supplemented those of Bernal[2] and Scott[3] which covered a far larger separation range.

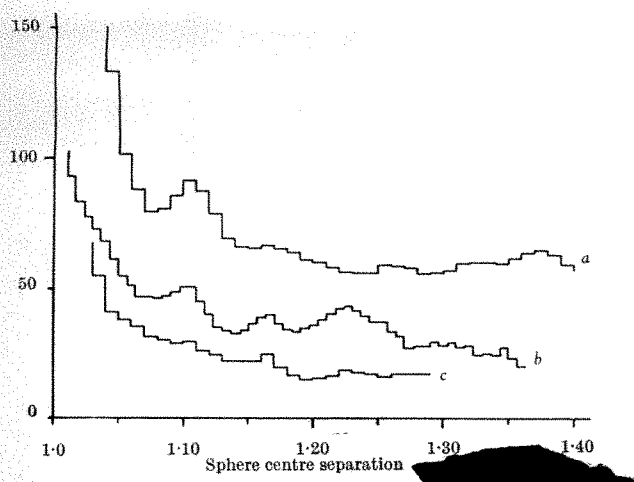

Fig. 1. Radial distribution function histograms; and Clark; *c*, Bernal.

The data were proc[illegible] two main separations

two spheres of the ring (Fig. 2*a* and *b*, 5–6). The sphere centre separation of this gap has been calculated as $\frac{4\sqrt{2}}{3\sqrt{3}} = 1{\cdot}0886\ldots$ diameters.

If another ring of five spheres is added to this first ring such that each sphere touches two adjacent spheres of the ring as well as one of the central pair, then five gaps are observed between these added spheres. Three of the gaps can be shown to be caused by a sphere centre separation of 1·0886 diameters (Fig. 2*c*, 12–8, 8–9 and 9–10), but the other two are greater. They are larger because one member of the new ring occupies a site above the original small gap and is therefore slightly below the plane of the other four new spheres. The sphere centre separation for these larger gaps can be shown to be $\frac{5}{\sqrt{19}} = 1{\cdot}14707\ldots$ diameters (Fig. 2*b*, 10–11 and 11–12).

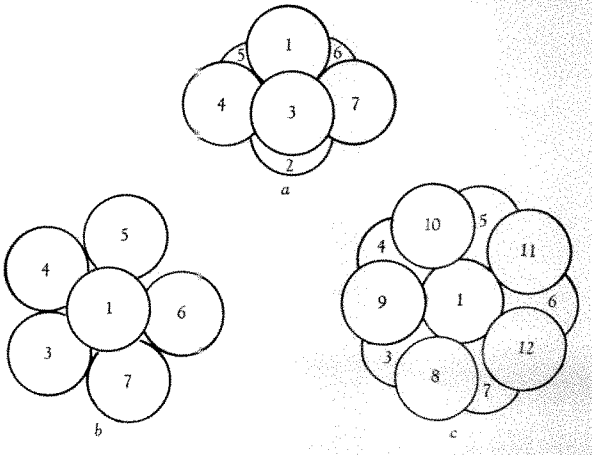

Fig. 2. Configurations containing small gaps.

These separations agree approximately with the first two small peaks of Fig. 1, but both are smaller than the actual separation peaks. It requires at least seven spheres and fifteen contacts to form the smallest gap. If one small separation is introduced somewhere in the fifteen contacts, then it is found that in five cases the 1·0866 diameters separation is reduced whereas in ten cases it is increased.

For the 1·14707 diameter separation it requires at least nine spheres and twenty-one contacts to form a configuration where the separation is possible. If each of these contacts is opened in turn it is found that five have little effect, six close the separation and ten open it. A rigorous [illegible] difficult than in the first case because [illegible] separations in the new layers but [illegible] introduced into the structure [illegible] en the two main separations

THE SOLID STATE

Oxygen-inhibited Grain Growth in Thin Films of Semiconducting Cuprous Iodide

THIN films, a few thousand angstroms thick or less, of various inorganic materials can be formed by the polycrystalline condensation of the low-pressure vapour on a cool substrate. Such films are gaining importance in optical elements, in electronic microcircuitry, and in devices for information storage.

It is common experience for the optical and/or electrical properties to change gradually with age after the film has been deposited, and numerous examples of such changes have been cited. It is evident, then, that the utility of thin films partly depends on limiting or controlling the changes of properties which occur on ageing. In a recent investigation of thin-film dielectric properties, Weaver[1] found recrystallization or grain growth to be a common result of ageing inorganic films. Grain growth caused extensive degradation of electrical properties. It is common practice nowadays when thin films are being deposited to temperature cycle or anneal the deposit in order to speed up ageing by encouraging changes in the growth of grains to occur more rapidly. Stabilizing the size of individual grains in a thin film is, therefore, a major problem in the search for stable optical and electrical properties.

Rutter and Aust[2] have shown that small amounts of soluble impurities can cause a considerable reduction in the rate of grain boundary movement in bulk metals. Ruhl[3] has suggested that impurities in a thin film of tin deposited at 20° K reduced the rate of grain growth during annealing at higher temperatures.

This report describes how small amounts of oxygen in thin films of cuprous iodide reduce the rate of grain boundary movement and stabilize the optical transmission for long periods of time. Previously, Herrick and Tevebaugh[4] reported the beneficial effect on the conductivity of thin films of cuprous iodide which resulted from the addition of small amounts of oxygen. Oxygen concentrations estimated at 10^{19} atoms per c.c. were produced by intentional burial of oxygen gas in the condensate during the vacuum condensation of copper vapour at room temperature. The thin condensate film was converted to cuprous iodide containing oxygen by brief treatment with iodine vapour. This treatment is not believed to alter [illegible]ntly the grain size of the film.

[illegible]prous iodide films 1000–1400 Å thick [illegible]terephthalate base have an average [illegible]0 Å. Spontaneous growth arising [illegible] of up to 4300 Å which are [illegible] growth can be followed

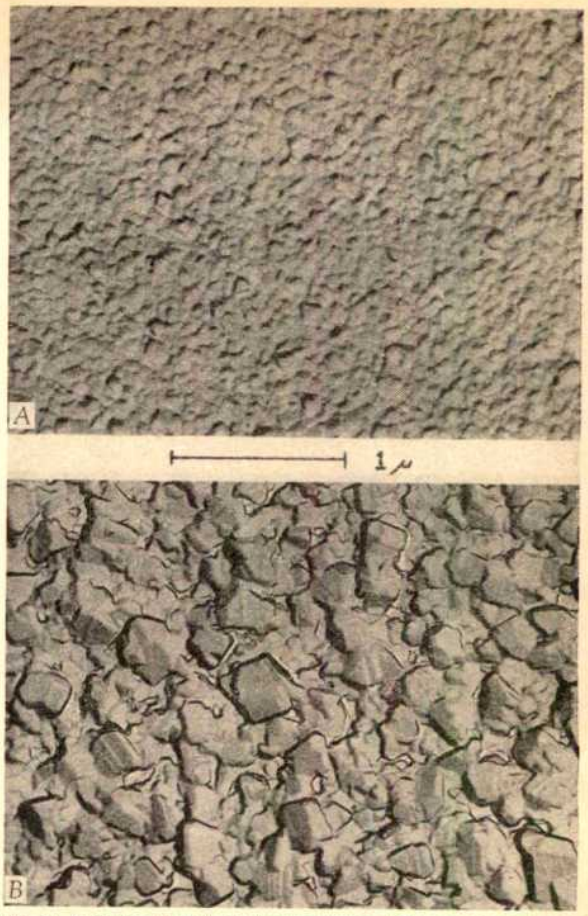

Fig. 2. Electron micrograph showing surface features of two cuprous iodide films from Fig. 1. Both films have aged 20 months at room temperature. *A*, 1 × 10^{-2} mm mercury oxygen pressure during copper condensation. *B*, 6 × 10^{-3} mm mercury oxygen pressure during copper condensation. (Platinum–carbon replicas, × 25,000.)

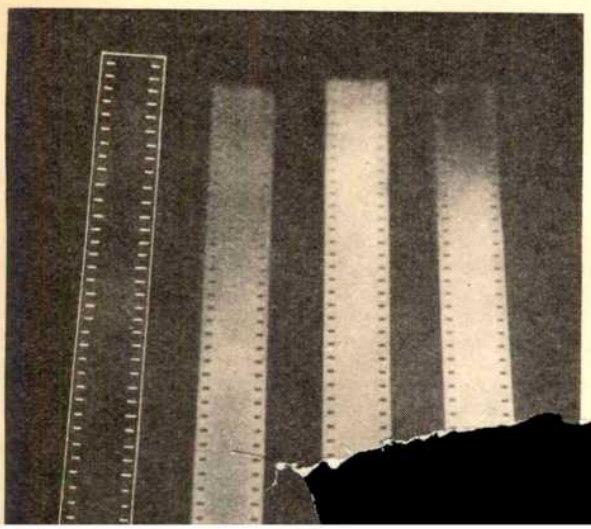

Fig. 2 shows electron micrographs of the surfaces of two films from Fig. 1—those having the greatest and the least oxygen contents. It is evident that the film with the highest oxygen content has almost maintained the original grain size after ageing 20 months. Over the same period, the film with least oxygen content has experienced extensive grain growth.

We conclude that the rate of grain growth was markedly slowed down in these experiments and that the effect probably resulted from the presence of oxygen in the film.

Crystallization of Penicillin in the Solid Phase

DURING experiments on the hygroscopicity of penicillin salts, an unusual behaviour of substantially pure freeze-dried potassium benzylpenicillin was noted.

On exposure to air, the material absorbed moisture at a steady rate, up to a maximum content of 7–14 per cent, apparently remaining in the solid state. Then suddenly, the material shrank to a more compact form and began to lose weight. At first the loss was rapid and then it continued at a diminishing rate until the specimen returned to its original weight.

The time required for the uptake and subsequent loss of moisture was variable and depended on the temperature and relative humidity of the air, and on the weight and compactness of the specimen. A specimen weighing 0·1 g would usually take up moisture for about 4 h, and then completely lose it in about 18 h.

That the abrupt change which occurred at the point of maximum moisture content is a spontaneous crystallization of substantially amorphous material is evidenced by the changes in physical properties summarized in Table 1.

Table 1. CHANGES IN PHYSICAL PROPERTIES OF POTASSIUM BENZYLPENICILLIN ON EXPOSURE TO MOIST AIR

Property	Freeze-dried specimen		Control specimen*
	Before exposure	After exposure	
Stability on heating at 120° C	Decomposed within 16 h	Stable for 96 h	Stable for 96 h
Heat of solution (cal/mole) (at concentration 0·055 M)	4,550 ± 130	910 ± 90	850 ± 90
Aggregate refractive index	1·56	1·58	1·58
Microscopic appearance between crossed Nicols	Almost entirely isotropic flakes	Largely crystallites evenly distributed in a mainly isotropic groundmass†	Well-formed crystals showing uniform extinction
X-ray diffraction pattern	Faint diffraction lines with broad halo of scattering at low angles of diffraction	More intense diffraction lines with much less intense halo	Very intense diffraction lines

* Crystallized from aqueous butanol.
† Crystalline areas showing single crystal characteristics (that is, uniform extinction) also occurred in many flakes of exposed material, especially along the edges of the flakes.

A similar spontaneous crystallization was observed with freeze-dried specimens of sodium benzylpenicillin and potassium phenoxymethylpenicillin. No such phenomenon was observed when calcium or procaine benzylpenicillin, phenoxymethylpenicillin (free acid) or calcium phenoxymethylpenicillin was exposed to moist air.

CHEMISTRY

Comparison of the Effect of Alpha- and Gamma-radiation on an Enzyme

EXTENSIVE investigations have been carried out on the effects of radiation on various organic polymers assuming that they could be regarded as model compounds for biological materials. Our previous work concerning the effects of gamma-rays on aqueous polymer solutions[1–3] revealed the existence of new effects resulting from the presence of water. Radiation-induced changes in the polymer may result either from the direct effect of the radiation on the solute molecules or from the indirect effect, that is, reactions of solute with reactive species such as hydrogen atoms, hydroxyl radicals or solvated electrons produced by irradiation of the water. The indirect effect becomes increasingly important as the concentration is reduced[4].

The radiation-induced reactions in solutions of macromolecules can be considerably affected by the presence of relatively small amounts of certain chemical additives. Some of the possible protection mechanisms can be envisaged to include the following: (*a*) Energy transfer between an excited macromolecule and the additive, the molecule being chemically unaltered. (*b*) Electron transfer from the additive to the polymer to replace an ejected electron before chemical changes in the molecule can occur. (*c*) True repair of a polymer radical by hydrogen transfer from the additive. (*d*) Stabilization repair of a solute radical by reaction with additive or additive radicals, the additive becoming incorporated into the molecular structure; the radical in this case becomes stabilized by modification as distinct from true repair. (*e*) The additive may react with radicals produced in the solvent before these can attack and modify the polymer; in this case protection is offered against the indirect effect and radiation damage is reduced without involving the macromolecule.

Our early research was carried out with γ-radiation; the effects of the more densely ionizing α-radiation on these systems is now being studied to provide a comparison between the effects of these two types of radiation and to point to possible differences in protection mechanisms. In the case of the densely ionizing α-radiation, track effects (reactions of primary reactive species with each other in the α-track before they have time to diffuse into the solution and react with the solute) have to be taken into account. This may lead to differences in the radiation effects on the macromolecules as well as on the protection.

The polymer solutions (polyvinylpyrrolidone, which is cross-linked in aqueous solution mainly by indirect action, and polyethyleneoxide, which is cross-linked mainly by the direct action of radiation) which we have investigated for γ-radiation do not lend themselves readily to a similar investigation using polonium-210 α-radiation. As an alternative system for this comparison, we have chosen solutions of yeast alcohol dehydrogenase. The irradiations were carried out with 0·1 ml. of 0·1 per cent solution in

special glass 'Melinex' cells at room temperature in the presence of air, with doses between 0·025 and 0·6 Mrads both with α- and γ-radiation. The residual activity of the irradiated alcohol dehydrogenase was determined spectrophotometrically at 340 mμ. Alcohol dehydrogenase, in the presence of nicotinamide adenine dinucleotide (NAD), catalyses the reaction to form acetaldehyde from ethanol, the nicotinamide adenine dinucleotide itself being reduced by this reaction. The method of analysis is to measure the velocity of the conversion of NAD to $NADH_2$ spectrophotometrically at a fixed wave-length (340 mμ). Yeast alcohol dehydrogenase has a reported molecular weight of 151,000 and contains about seven thiol groups per molecule on which it depends for its activity. The results shown in Fig. 1 indicate the usual exponential decrease in activity.

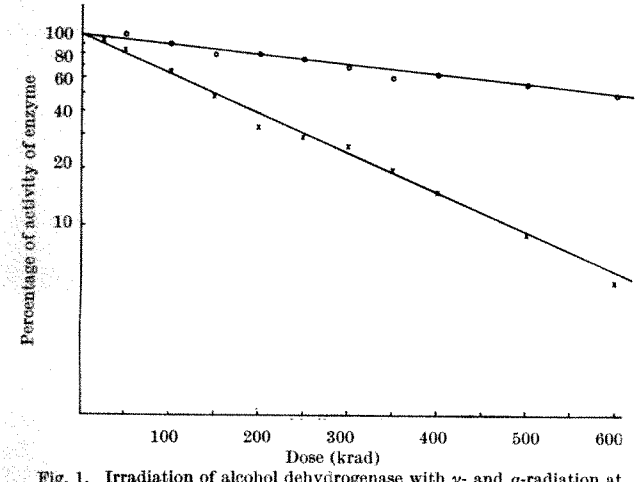

Fig. 1. Irradiation of alcohol dehydrogenase with γ- and α-radiation at room temperature in air. ○, Irradiation by polonium α-particles; ×, irradiation by cobalt-60 γ-rays. *p*H 7·9 to 8·0 adjusted with HCl.

It was found that the loss of activity of alcohol dehydrogenase was 44 per cent for a dose of 500 krads of α-radiation against 91 per cent for a dose of 500 krads γ-radiation. 44 per cent inactivation of the enzyme is brought about by a γ-dose of 125 krads, which means that γ-radiation is about four times as effective as α-radiation in inactivating alcohol dehydrogenase in aqueous solution.

For these 0·1 per cent solutions we can evaluate the average energy absorbed per enzyme molecule inactivated. If only the energy absorbed directly by the enzyme is considered, a dose of 500 krads of γ-rays given to a molecule of average molecular weight 151,000 amounts to:

$$E = \frac{5\times10^5\times0{\cdot}625\times10^{14}\times1{\cdot}51\times10^5}{6\times10^{23}} = 7{\cdot}8 \text{ eV}$$

However, this dose gives a considerable amount of deactivation (91 per cent). If r_0 is the average (37 per cent) inactivation dose,

$$\frac{n}{n_0} = \exp(-r/r_0)$$

where $n/n_0 = 0{\cdot}09$, $r = 5\times10^5$ rads so that $r_0 = 2{\cdot}07\times10^5$ rads; the average energy absorbed per enzyme molecule inactivation,

$$E_0 = 7{\cdot}8\,\frac{2{\cdot}07\times10^5}{5\times10^5} = 3{\cdot}2 \text{ eV}$$

This value is far lower than is common in the destruction of a homopolar bond. We must therefore assume an indirect effect, resulting from the radiolytic products formed in the water. If all the energy absorbed by the solution is transferred in this way, the value of E_0 increases to the high value of 3,200 eV energy absorbed in the solution per enzyme molecule inactivated. Such a high value may be reached owing to: (*a*) the very dilute nature of the solution; (*b*) self-protection of the enzyme owing to the thiol groups. Analogous measurements with very dilute solutions of γ-irradiated trypsin lead to a value of only 25 eV per trypsin molecule inactivated. Thus the former explanation cannot be sustained.

For α-radiation the average inactivation energy is four times greater, again emphasizing the recombination of particles within the α-track. Preliminary protection experiments have indicated that thiourea, cysteamine, cystamine, cystine and cysteine at low concentrations ($M\times10^{-4}$) protect the enzyme against both γ- and α-radiation. All these additives were found to be efficient protecting agents against γ-radiation in our polymer systems. This is being further investigated and more detailed results will be published later.

Fluorescence Quantum Efficiencies of Octa-coordinated Europium Homogeneous and Mixed Chelates in Organic Solvents

Certain octa-coordinated europium chelates dissolved in organic solvents have been shown to be suitable liquid laser materials[1–4]. Determinations of fluorescence quantum efficiency for these compounds in solution are essential for their evaluation as potential candidates for efficient laser performance as well as for an understanding of the processes associated with the overall energy transfer.

The measurements of fluorescence quantum efficiency reported by Gudmundsen *et al.*[5] and Winston *et al.*[6] for europium theonyltrifluoroacetonate in ethanol, toluene and acetone were carried out with a chelate of undetermined composition. Bhaumik and Telk[7] reported fluorescence quantum yield values for europium complexes of three β-diketone ligands in actone, dimethylformamide (DMF), a mixture of ethyl alcohol and methyl alcohol, and a mixture of ether-isopentane-ethyl alcohol (EPA) at 300° K, 100° K and 77° K.

We have determined the relative fluorescence intensities of europium β-ketoenolates with different substituents attached to the chelate ring in solvents of various polarity in the freezing point–boiling point temperature range[8]. This communication reports the quantum efficiency of several octa-coordinated europium homogeneous (same ligand) and mixed (different ligand groups) chelates in a number of solvents at 25° C. These chelates were carefully prepared, purified, and well characterized by elemental analysis to correspond to the designated formula. Synthesis procedures for the ligands and their europium complexes have previously been described[9–11]. The following europium chelates were prepared: *tetrakis*(theonyltrifluoroacetonate)piperidinium (EuT_4P), *tris*(theonyltrifluoroacetonate)dipyridyl (EuT_3Dipy), *tris*(theonyltrifluoroacetonate)phenanthroline (EuT_3Phen), *tetrakis*(benzoylacetonate)piperidinium (EuB_4P), *tris*(benzoylacetonate)dipyridyl (EuB_3Dipy), *tris*(benzoylacetonate)phenanthroline (EuB_3Phen), *tetrakis*(dibenzoylmethide)piperidinium (EuD_4P), *tris*(dibenzoylmethide)dipyridyl (EuD_3Dipy), *tris*(dibenzoylmethide)phenanthroline (EuD_3Phen), *tetrakis*(benzoyltrifluoroacetonate)piperidinium ($EuBt_4P$), *tetrakis*(2-naphthoyltrifluoroacetonate)piperidinium ($EuNt_4P$), and *tetrakis*(dianisoylmethide)piperidinium ($EuDA_4P$). 'Spectro' grade acetonitrile, dimethylformamide and benzene were used without further purification. Absolute ethanol and butyronitrile were purified by repeated distillation from magnesium ethoxide

and anhydrous magnesium sulphate respectively. 10^{-3} molar solutions of chelate were freshly prepared before each determination. An Aminco-Bowman spectrophotofluorimeter was used to record the apparent fluorescence spectra in the front-surface arrangement. At the concentrations used, the exciting light (360 mμ) was completely absorbed for all chelate solutions in a thin layer near the front window of the cell. Correction factors were determined both for the exciting unit (xenon arc, monochromator, slits) and the detector system (slits, monochromator, *R*136 red-sensitive photomultiplier) by known procedures[12-14]. The corrected fluorescence spectra of chelate solutions were plotted against wave number and the area under the true fluorescence spectrum was calculated and compared with that obtained with freshly prepared solutions of rhodamine *B* in ethyl alcohol and eosin, in both ethyl alcohol and 10 N sodium hydroxide. The concentration of these two standards of known quantum efficiency was adjusted so that the optical density of the solutions was equal to that of the different chelates at the exciting wavelength. Rhodamine *B* in ethyl alcohol has a quantum efficiency of 0·69 (ref. 12), and eosin in ethyl alcohol or 10 N sodium hydroxide of 0·23 respectively[12].

Table 1 gives the results found for dimethylformamide (DMF) and acetonitrile (CH_3CN) for 10^{-3} M chelate solutions. The quantum efficiencies for the three chelates having a trifluoromethyl group were determined in addition to the two solvents mentioned in benzene (C_6H_6), ethanol (EtOH), and butyronitrile (C_3H_7CN). The values are given in Table 2.

Table 1

Chelate	Quantum efficiency in DMF	CH_3CN
EuT_4P	0 615	0 632
EuT_3Dipy	0 503	0·163
EuT_3Phen	0·365	0·123
EuB_4P	0·063	0 038
EuB_3Dipy	0 074	Insol.
EuB_3Phen	0 075	0·092
EuD_4P	0·074	0 067
EuD_3Dipy	0·058	Insol.
EuD_3Phen	0·040	0·049
$EuDA_4P$	0·035	Insol.

Table 2

Chelate	CH_3CN	Quantum efficiency in C_6H_6	C_3H_7CN	DMF	EtOH
EuT_4P	0·632	0 221	0·633	0 615	0·151
$EuBt_4P$	0·578	0·295	0·624	0·473	0·230
$EuNt_4P$	0·580	Insol.	0 585	0·561	0 354

The results were found to be reproducible to within 1 per cent. Removal of oxygen from solutions did not change the quantum efficiencies to any significant extent.

The quenching which results in decrease of the quantum efficiency is attributed to radiationless deactivation arising from vibronic coupling of the energy levels in both ligand and rare earth ion either intramolecularly or to the surrounding solvent molecules. The results in Table 2 are consistent with a higher quantum efficiency for the dissociated species $EuL_4^{\ominus}$ as compared with the neutral species EuL_4P (*L* is the ketoenolate anion). We have shown previously from molecular weight and conductivity measurements[15] that the fluorinated *tetrakis* chelates are essentially heterolytically dissociated in acetonitrile and DMF and undissociated in non-polar solvents such as benzene. This suggests strong intramolecular quenching at the organic cation site, probably through coupling of the electronic energy levels to vibrations of the two N—H bonds in the piperidinium cation. This is possible only in the undissociated *tetrakis* chelates. The low quantum efficiency in alcoholic solution has been attributed to the presence of the high energy vibrations of the O—H bonds in the solvent and confirmed by the significant improvement in quantum efficiency obtained with deuterated hydroxylic solvents[7,16,17]. In general, mixed chelates have lower quantum efficiency than the corresponding homogeneous *tetrakis* complexes. Butyronitrile is slightly superior to acetonitrile and DMF as a liquid laser host for europium ketoenolates.

Correlation between Chemi-ionization in Flames containing Organic Fuels and the Heat of Oxidation of the Carbon in the Fuel Molecule

THE "chemi-ionization" which occurs when organic compounds are burned, either alone or mixed with hydrogen, in oxygen or air has received much attention. Data obtained by means of the flame ionization detector used in gas chromatographic work[1-4], and studies of ionization in flames at reduced pressure[5], show that when a variety (and sufficiently large number) of organic compounds is examined, certain regularities of behaviour become apparent. First, when traces of such a compound are introduced into a hydrogen/oxygen/nitrogen flame, the number of free electrons produced is proportional to the concentration of the compound in the flame gases. Secondly, for equimolar concentrations of compounds which are members of the same homologous series, the number of electrons varies linearly with the number of carbon atoms in the molecule. Thirdly, when the compound contains C=C or C≡C bonds[5], the number of electrons is increased with respect to the corresponding paraffin, and reduced when it contains oxygen.

These and other data of a similar nature have been used in the past to support specific reaction schemes for chemi-ionization, and the one which seems to have gained most support[5-7] is the reaction originally proposed by Calcote[8]: $CH + O \rightarrow CHO^+ + e^-$. On the other hand, workers interested primarily in the applications of the flame ionization detector have attempted to estimate atom and group responses[9] on the basis of the known responses of the detector to various compounds. Dewar[2] has also attempted to correlate the relative responses with the changes in bond energy involved in forming carbon dioxide from carbon atoms, disregarding completely the bond energies of any links broken in the oxidation.

The purpose of this communication is to direct attention to a striking correlation which seems to exist between

the relative number of electrons produced by a given organic compound $C_xH_yO_z$, and the heat of the reaction:

$$C_xH_yO_z + O_2 \rightarrow CO_2 + H_2 \quad (1)$$

(which is equivalent to the heat of combustion of the compound minus the heat of formation of any resulting water—at least for substances containing carbon, hydrogen and oxygen only). The heat of reaction (1), calculated from the heats of combustion and the heats of formation given in refs. 10 and 11, is plotted in Fig. 1 against the number of carbon atoms in the molecule for a selection of paraffins, olefines, acetylenes, benzenes, aliphatic alcohols, ketones, esters and acids. In Fig. 2 the relative steady-state numbers of free electrons obtained per fuel molecule burned in stoichiometric, premixed flames with oxygen at reduced pressure[5] are plotted in a similar fashion for most of the same compounds. The similarity between Figs. 1 and 2 is indeed marked.

An apparent point of difference is that the curves for the various types of compounds are more widely separated in Fig. 2 than in Fig. 1. It should be borne in mind, however, that the ordinates in Fig. 2 represent relative steady-state concentrations of free electrons under flame conditions, that is, they are partly determined by the process responsible for the removal of the charged species

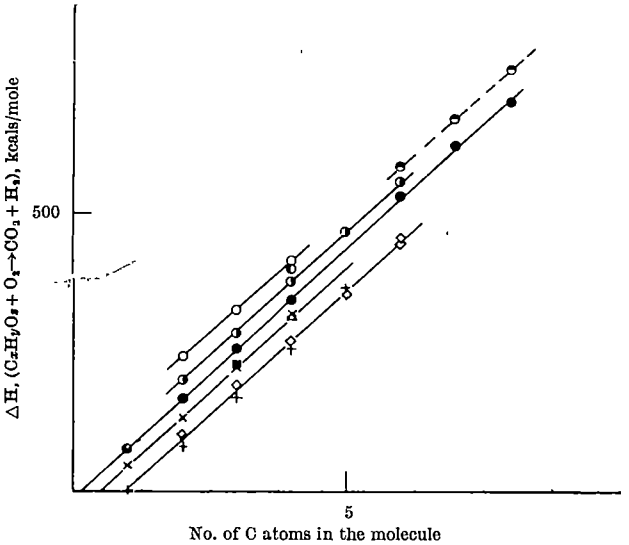

Fig. 1. Heats of oxidation of carbon in various molecules. ΔH, $(C_xH_yO_z + O_2 \rightarrow CO_2 + H_2)$ versus the number of carbon atoms in the molecule, for paraffins (●), olefines (◑), acetylenes (○), benzenes (◓), alcohols (×), ketones (■), ethers (△), esters (◇) and acids (+).

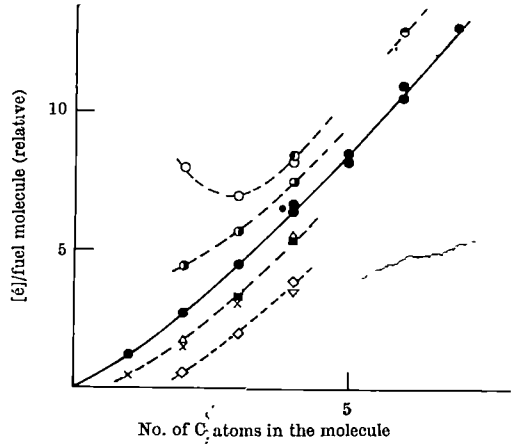

Fig. 2. Relative ionization in stoichiometric flames of various fuels (at reduced pressure). [e⁻]/fuel molecule (relative) versus the number of carbon atoms in the molecule, for paraffins (●), olefines (◑), butadiene (◐), acetylenes (○), benzene (◓), alcohols (×), ketones (■), ether (△), dioxane (▽) and esters (◇).

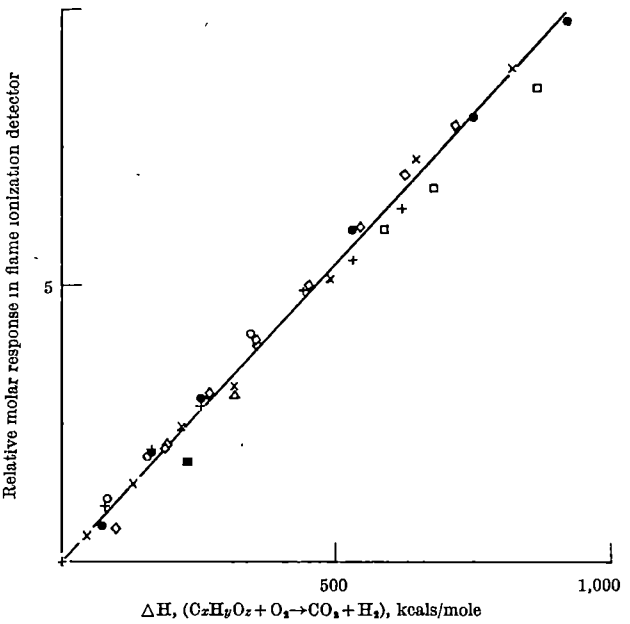

Fig. 3. Relative numbers of ions produced from various compounds as a function of the heat of oxidation of carbon in the molecule. Relative molar response in flame ionization detector versus ΔH, $(C_xH_yO_z + O_2 \rightarrow CO_2 + H_2)$, for paraffins (●), alcohols (×), ketones (■), ethers (△), esters (◇), acids (+), aldehydes (□) and glycols (○).

above the reaction zone. On this account it would no doubt be more satisfactory to use the relative responses of compounds in the flame ionization detector as ordinates in Fig. 2; such responses should represent the maximum rates of production of free electrons in a specified flame and be independent of the recombination processes. These ionization detector data were not used, however, because although they fall into the same pattern as the steady-state results for most classes of compounds, it appears that olefines and aromatic hydrocarbons do not give any more ions than the corresponding paraffins[3,4]. It is possible that this results from incomplete decomposition of these particular molecules on passage through the small diffusion flames[9] usually used in this type of work.

In Fig. 3 the relative ionization detector responses obtained by Perkins *et al.*[4] for paraffins, aliphatic alcohols, esters and acids are plotted against the heat of reaction (1). It can be seen that at least for these compounds there is a linear relationship between the two quantities.

The implications of this relationship will not be discussed fully here, except to note that it supports earlier conclusions[2,5] that from the point of view of ionization the molecule is shattered into single carbon atom units. It also suggests that the overall energy required to produce the ionization is related to that deriving from the complete oxidation of carbon in any particular molecule, without any apparent contribution from the oxidation of the hydrogen contained in the molecule.

Attention might also be directed to the fact that at least some carbon compounds which contain no hydrogen give rise to measurable responses in the ionization detector when added to a hydrogen flame—for example, carbon tetrachloride, dicarbon tetrachloride (ref. 3) and carbon disulphide (ref. 2). Moreover, if the relative responses for the chloromethanes and chloroethylenes[3] (scaled by comparison with *n*-heptane) are plotted against the heat of the hypothetical reaction:

$$C_xH_yCl_n + O_2 \rightarrow CO_2 + H_2 + Cl_2 \quad (2)$$

analogous to reaction (1), the points fit the straight line of Fig. 3 quite well. This would seem to eliminate the necessity for a C—H bond in the original molecule in order for the chemi-ionization to occur. The observation of

Sternberg *et al.*[9] that traces of carbon tetrachloride in carbon monoxide flames give rise to ions with an efficiency similar to methane appears to eliminate the suggestion that hydrogen participates in any form. However, this result must be regarded as inconclusive because apparently no precautions were taken to exclude all traces of moisture from the gases used.

I should like to acknowledge an I.C.I. Fellowship.

Separation of Coumarins

SORPTION on cation exchange resins allows the complete separation of some coumarins[1] in dilute solution using a simple technique. A column of the styrene-divinylbenzene copolymer-type sulphonic acid cation exchange resin, Dowex 50 *W-X* 4 (−100, +200 mesh, Dow Chemical Co.), in the hydrogen form (bed length, 53 cm; bed volume, 131 c.c.) has been used for this purpose.

The coumarins investigated are divided into two groups. Group *A* includes coumarin, 7-hydroxycoumarin, 8-hydroxycoumarin and 7,8-dihydroxy-4-methyl coumarin; Group *B* includes 7-methylcoumarin, 3,4-dimethylcoumarin, 7-methoxycoumarin, 6-methoxy-4-methylcoumarin and 6,7-dimethoxy-4-methylcoumarin.

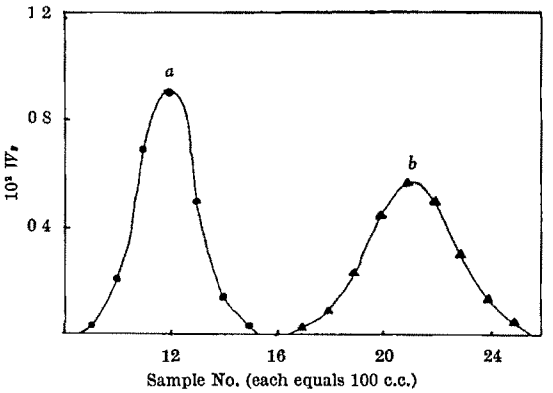

Fig. 1. Separation of (*a*) 7-hydroxycoumarin ($W = 2\,508 \times 10^{-5}$) and (*b*) 7-methoxycoumarin ($W = 2\,446 \times 10^{-5}$). W, solute content in m.equiv/100 c.c. of solution and sorbed on the resin bed. W_r, No. of m.equiv. of solute in 100 c.c. of effluent sample.

100 c.c. of solution (~5–6 × 10^{-4} M) in 10 per cent methanol (by volume), containing only one compound from each group, was passed through the column at the rate of 5 c.c./min and the run was then continued with 10 per cent methanol (by volume) as influent, to elute the sorbed solutes on the column. The effluent was collected in samples and estimated for solute content by ultraviolet absorption[2]. Each compound was eluted separately. Fig. 1 shows the separation obtained with a mixture of 7-hydroxycoumarin and 7-methoxycoumarin.

Chloro-olefine Complexes of Platinum

ALTHOUGH the reactions of fluoro-olefines with transition metal complexes have yielded very stable fluoro-olefine and fluorocarbon complexes[1–3] analogous reactions with chloro-olefines have hitherto resulted in chlorination to form metal chlorine bonds[4–6]. We find, however, that on refluxing a benzene solution of $Pt(PPh_3)_4$ (ref. 7) with tetrachloroethylene the complex $(Ph_3P)_2PtC_2Cl_4$ is formed in high yield as white air stable crystals with a melting point of 278° C dec. This would seem to be the first example of a perchloro-olefine transition metal complex. The reaction of $Pt(PPh_3)_4$ with a number of halogeno-olefines, for example, tetrafluoroethylene, trichloroethylene, *trans*-dichloroethylene, 1,1,1-trifluoro-2,3,3-trichloro-2-propene, appears to be a general reaction for the preparation of complexes of the type $(Ph_3P)_2Pt$ olefine. The complexes prepared in this work and the recently described tetracyanoethylene[8] complex are considerably more stable than the olefine complexes of this type which were originally prepared with *trans*-stilbene, *trans* 4,4, dinitrostilbene and acenaphthylene[9].

The infra-red spectrum of the tetrachloroethylene complex shows bands owing to carbon chlorine vibrations at 910, 804 and 796 cm^{-1}. The other chloro-olefine complexes also show carbon chlorine bands in this region of the infra-red. No band that can be attributed to a C=C stretching frequency[10] is observed in the infra-red spectra of the tetrachloroethylene and trichloroethylene complexes between 2,000 and 1,500 cm^{-1}. The compounds are probably best regarded as complexes of Pt (II), the olefine forming a three membered ring with the platinum by way of two σ bonds.

Doubly charged Negative Ions of Oxygen, Fluorine, Chlorine and Bromine

ELECTRON impact processes give rise to both positive and negative ions. The negative ions are, in general, only about 10^{-3} times as intense as the positive ions. In contrast with positive ions, only singly charged negative ions have previously been reported. Calculations involving the crystalline state, where doubly charged negative ions (such as $O^=$ and $S^=$) apparently do exist, indicate that the formation of $O^=$ from O^- requires 7·8 eV in the gas phase[1]. The lifetime of a doubly charged ion in the gas phase would be expected to be short and has been predicted to be 10^{-10} sec or less[2]—too short for observation

in the usual mass spectrometer. This communication reports the observation of doubly charged negative ions of oxygen, fluorine, chlorine and bromine, with indications that the lifetimes are of the order of 10^{-4} sec (the ion collection time in the mass spectrometer used).

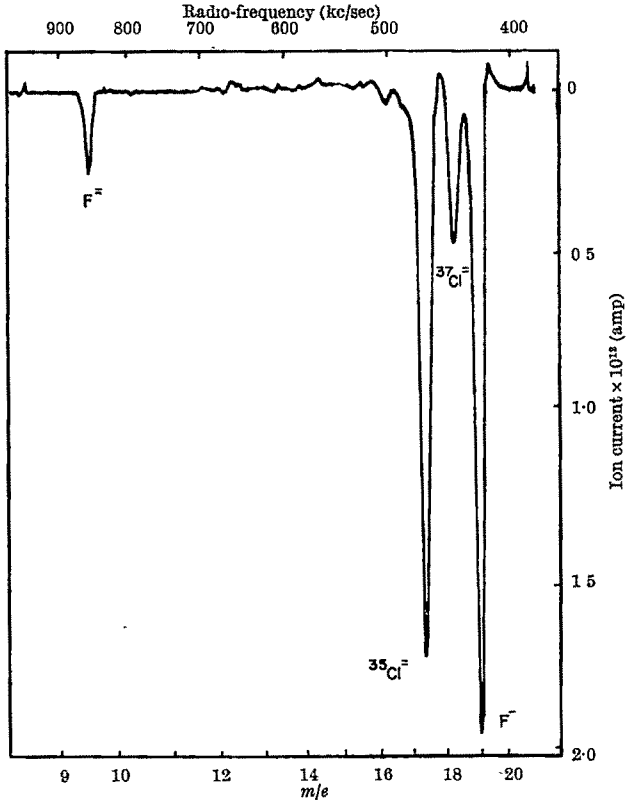

Fig. 1. Partial negative ion mass spectrum of CF_3Cl. The $^{35}Cl^-$ and $^{37}Cl^-$ peaks are not shown, but have an intensity of about ten times the $^{35}Cl^=$ and $^{37}Cl^=$ peaks. Electron energy, 70 V, trap current, 2 μamp; trapping potential, −0·75 V, radio-frequency voltage, 5 V/cm, 5 kG magnet.

We have observed these doubly charged negative ions in the mass spectra of carbon monoxide, oxygen, carbon tetrachloride, carbon tetrafluoride, CF_3Cl, CF_3Br and CF_2Cl_2, together with the expected singly charged negative ions oxygen, fluorine, chlorine and bromine. In the cases of CF_3Cl, CF_3Br and CF_2Cl_2, where both halogens are present, singly and doubly charged negative ions were observed for both halogens. A typical spectrum which shows F^-, $Cl^=$ and $F^=$ is presented in Fig. 1. Mass analysis was performed with an omegatron mass spectrometer. This instrument was developed for study at low masses[3], where resolution is usually very high. Resolution, however, is an inverse function of mass in the usual omegatron units—a fact which has limited the application of this unique instrument. The omegatron functions basically as a small cyclotron with the very important distinction that the radio-frequency electric field is applied across the entire analysing region and not just between the faces of two "D's" as in the cyclotron. This eliminates the possibility of harmonics in the omegatron operation[4]. (Our investigations confirm that the doubly charged negative ions which we observed do not arise from harmonics, but rather have the properties of a doubly charged species. This conclusion is based on studies of the effects of variations of pressure, trapping potential, electron beam current, and radio-frequency voltage. Peaks at multiples of the resonant frequency were not observed.) An ion the resonance frequency of which is equal to the applied radio-frequency, gains energy from the field continuously and generates an Archimedes spiral until the ion strikes the target electrode and is detected. A mass spectrum is obtained by recording the ion current as a function of the radio-frequency applied. Ions not detected are out of phase with the radio-frequency field, cannot gain energy continuously from the field, and therefore do not exceed a radius which is significantly less than the radius to the detector. Non-resonant ions thus generate complex rosettes[3]. A distinguishing characteristic of the omegatron is the fact that not all ions are extracted from the ion source.

The ion source used was essentially that of the General Electric ion resonance mass spectrometer. Measurements were made with a nominal electron energy of 70 eV at ion source pressures of the order of 10^{-5} torr and a trap current of 2 amp. Negative ions were selected for study by the application of a variable trapping voltage. By applying a negative d.c. voltage to two plates symmetrically placed on either side of the electron beam, instead of a positive charge which has been routinely used in the omegatron, not only are the negative ions held in the plane of the detector to increase sensitivity but also positive ions can be partially or completely removed (depending on the d.c. potential) from the ion beam. A General Radio type 1001*A* signal generator was used together with a Keithley model 610*A* electrometer and a permanent magnet of 5 kG.

It is apparent from the spectra of these compounds (see Fig. 1) that the doubly charged negative ions are fairly intense. No doubly charged negative species was noted in other negative ion mass spectrometric studies of these compounds; this eliminates consideration of the highly improbable process whereby an atom may capture two electrons simultaneously to form the doubly charged negative ion. However, it is possible for secondary processes to occur in the omegatron[5]. Consider the path of a non-resonant ion: after formation by electron impact, it is accelerated from the electron beam only to reach some maximum radius and then pass back through the electron beam again. Thus, for example, when a radio-frequency is selected which corresponds to an m/e value of 17·5 ($^{35}Cl^=$), the $^{35}Cl^-$ resonance frequency is not the same as the applied radio-frequency and $^{35}Cl^-$ would follow a non-resonant ion path. When the ion passes back through the electron beam, it is possible in the interaction of the singly charged negative ion and the electron beam to form a doubly charged negative ion. Alternatively, two non-resonant Cl^- ions may interact to form the observed $Cl^=$. The Cl^- ion intensity has been observed to increase linearly with the electron beam current while the $Cl^=$ ion intensity is very nearly a square function of the electron beam current. This is the dependency dictated by either of the mechanisms proposed here. Furthermore, these mechanisms give some indication of why doubly charged negative ions can readily be observed in an omegatron mass spectrometer.

We thank Esso Research and Engineering Co., Baton Rouge, Louisiana, for the gift of the ion resonance mass spectrometer which was modified and used in this investigation.

Gas–Solid Chromatographic Separation of Atmospheric Gases on Activated Alumina

SEPARATION of oxygen, nitrogen and carbon dioxide by gas–solid chromatography has been accomplished on multiple columns of different adsorbents[1,2]. Greene *et al.*[3] almost achieved this separation on activated charcoal, but resolution of oxygen and nitrogen with this adsorbent was incomplete.

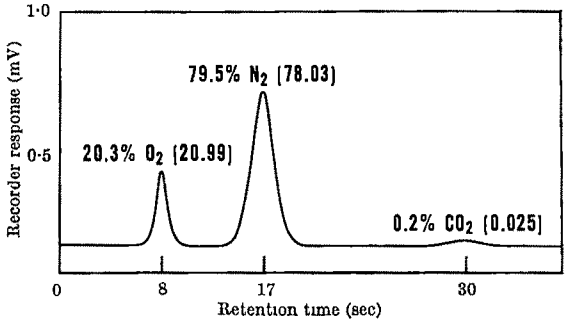

Fig. 1. Chromatogram of air gases from an alumina column purged with carbon dioxide. Figures in parentheses are values for the composition of dry air. Instrument: Beckman GC-4 Column, 4 ft. × 1/8 in. aluminium packed with 60/80 mesh *F*-20 'Microtek' alumina (activated by passing helium carrier through it for 1 h while at 350° C sample size, 15 μl. injected by way of sampling valve; carrier, helium, at 30 c.c./min; detector, thermal conductivity, operated at 25° C, 235 m.amp; attenuation, × 5; chart speed, 12 in./min.

Fig. 1 is a chromatogram of air gases from a single 4-ft. column of 'Microtek' alumina operated isothermally at 0° C. Because alumina at low temperatures tends to adsorb carbon dioxide irreversibly[4], the column was first purged with that gas for 1 h at 0° C to reduce adsorbent activity. Peak area percentages for both oxygen and nitrogen are in close agreement with the known composition of air. The somewhat high value for carbon dioxide probably resulted from dry ice used during the experiment. Column purge with carbon dioxide is necessary and important to its quantitative elution from alumina. Analysis of pure nitrogen, after the carbon dioxide purge, indicated no carbon dioxide displacement—only the nitrogen peak eluted. To ensure carbon dioxide peaks of reproducible area, it was necessary to carry out the purge often—preferably once every 3 h for about 15 min. Any gradual loss of carbon dioxide during column use would be shown by a slow rise in the chromatogram baseline. This was not observed when the purge was carried out regularly. Because irreversible adsorption effects are strong enough to remove carbon dioxide from air mixtures if purging is neglected, a carbon dioxide "peak" from a saturated column operated isothermally can only appear when carbon dioxide is introduced in amounts that exceed the adsorbed saturation concentration.

Although the Beckman *GC*-4 chromatograph was equipped with a low-temperature accessory for oven cooling, this attachment was not used. Instead, to check amenability of the separation technique to instruments of less refinement, dry ice in a paper cup was placed in the oven. The oven atmosphere was cooled as the airstream from the circulating fan was continuously passed over the surface of the dry ice. Inlet and exhaust ports, feed lines, and the detector compartment were operated at room temperature to maximize detector sensitivity[5]. Air samples of 15 μl. were routed to the column through a gas sampling valve, although chromatograms could be exactly duplicated by syringe injections of equivalent volumes.

Activated alumina offers a convenient means by which air gases can be analysed. Its use allows the analyst to operate his instrument under the best possible conditions of flow and temperature and also results in fast, reproducible chromatograms.

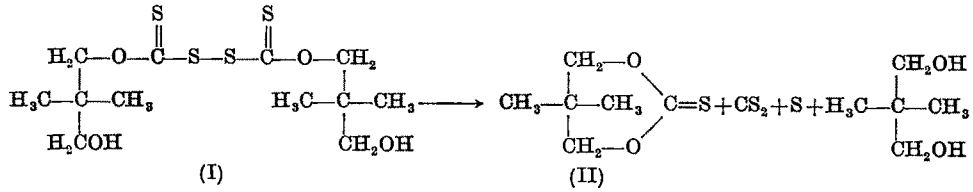
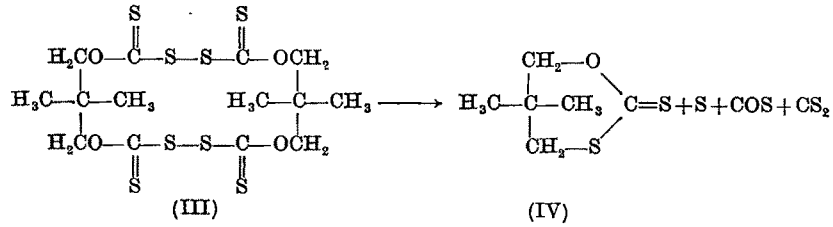
Rearrangement of *Bis*(o-thiocarbonyl) Disulphides

IN recent work[1] we showed that *bis*(1,2-*o*-isopropylidene-3-*o*-thiocarbonyl-α-L-glucofuranose) disulphide rearranged on standing in basic organic solvents to give equimolar amounts of carbon disulphide, elemental sulphur, 1,2-*o*-isopropylidene-α-D-glucofuranose, and 1,2-*o*-isopropylidene-α-D-glucofuranose 5,6-thionocarbonate. That work has now been extended to an investigation of *bis*(*o*-thiocarbonyl) disulphide derivatives (referred to as xanthides) of 1,2-, 1,3-, 1,4-, L5-, and 1,6-dihydroxy alkanes.

The monoxanthates of the diols were prepared by treating the diol compound or its dioxane solution with 1 molar equivalent of sodium hydroxide (5 N) and excess carbon disulphide. The corresponding xanthides were prepared by treating the xanthates with iodine solution.



The monoxanthide of 1,2-propanediol on standing either at 25° C for 3 days or in anhydrous pyridine at 25° C for 3 h rearranged to yield equimolar amounts of 1,2-propanediol, 1,2-propane thionocarbonate, carbon disulphide, and elemental sulphur.

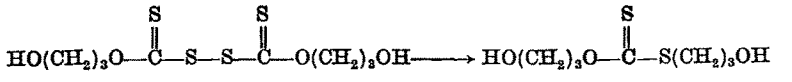


The thionocarbonate was recovered as an oil. Analysis showed a sulphur content of 27·6 per cent; the sulphur content calculated for $C_4H_6O_2S$ is 27·1. The ultra-violet spectrum showed λ_{max}^{MeOH} 234 mμ (ε 13,800). The extinction coefficient of 1,2-*o*-isopropylidene-α-D-glucofuranose 5,6-thionocarbonate at 234 mμ was 15,700.

The monoxanthide of 2,2-dimethyl-1,3-propanediol (I) was recovered in an overall yield of 43 per cent as a yellowish crystalline compound, m.p. 103–106°; λ_{max}^{MeOH} 240 mμ (ε 20,000), 285 mμ (ε 11,400). Analysis showed: carbon, 39·2; hydrogen, 6·1; sulphur, 36·0. The values calculated for $C_{12}H_{22}O_4S_4$ are: carbon, 40·2; hydrogen, 6·1; sulphur, 35·7. When (I) was allowed to stand in anhydrous pyridine at 45° C for 4 h, equimolar amounts of carbon disulphide, elemental sulphur, and the cyclic thionocarbonate derivative (II) of 2,2-dimethyl-1,3-propanediol were identified. Compound II was crystalline, m.p. 101°, λ_{max}^{MeOH} 244 mμ (ε 14,500) and its structure was formulated on the following basis: elemental analysis gave the empirical formula $C_6H_{10}O_2S$. Found: carbon, 49·5; hydrogen, 6·9; sulphur, 21·7; molecular weight, 138 (vapour pressure osmometry in acetone); calculated for $C_6H_{10}O_2S$: carbon, 49·3; hydrogen, 6·9; sulphur, 21·9; molecular weight, 146. The infra-red spectrum showed no hydroxyl absorption. The presence of a C=S group was shown by a positive iodine-sodium azide test[2] and by

converting II quantitatively to the known cyclic carbonate[3] on treatment with silver nitrate. The thionocarbonate II was prepared independently by treating a dioxane–pyridine solution of 2,2-dimethyl-1,3-propanediol with thiophosgene by a procedure reported previously[1].

(I) (II)



(III) (IV)

When a dioxane solution of 2,2-dimethyl-1,3-propanediol was treated with a large excess of sodium hydroxide (12 N) and carbon disulphide, the dixanthate was obtained. Treatment with iodine gave the corresponding crystalline dixanthide (III) in a 40 per cent yield, m.p. 183–185°, λ_{max}^{MeOH} 99 per cent–dioxane 1 per cent 240 mμ (ε 18,600), 285 mμ (ε 6,400). Found: carbon, 33·0; hydrogen, 3·9; sulphur, 49·0; molecular weight, 500 (Rast in camphor): calculated for $C_{14}H_{20}O_4S_8$: carbon, 33·0; hydrogen, 3·9; sulphur, 50·4; molecular weight, 508. The dixanthide was recovered unchanged on treating with pyridine at room temperature for 18 h, but on heating on a steam bath for 30 min, III decomposed with rearrangement to give elemental sulphur, carbon disulphide, carbonyl sulphide, and a cyclic dithiocarbonate derivative (IV).

The dithiocarbonate (IV) was recovered in 95 per cent yield as a crystalline solid, m.p. 62–63°; λ_{max}^{MeOH} 225 mμ (ε 5,300), 295 mμ (ε 12,000). Found: carbon, 44·4; hydrogen, 6·2; sulphur, 39·1; molecular weight, 162 (vapour pressure osmometry in acetone). Calculated for $C_6H_{10}OS_2$: carbon, 44·5; hydrogen, 6·2; sulphur, 39·6; molecular weight, 162.

The monothiocarbonate derivative of compound IV was obtained as a syrup on reflux of an acetone solution of IV with a saturated solution of potassium permanganate. Found: sulphur, 21·4; calculated for $C_6H_{10}O_2S$: sulphur, 21·9. The course of oxidation was followed spectrometrically and, by the end of the reaction, practically no absorption occurred at 295 mμ while a strong carbonyl peak showed at 5·9μ. Alkaline hydrolysis of an alcoholic solution of the monothiocarbonate derivative at 25° gave 1 molar equivalent of sulphydryl derivative as revealed by iodine titration.

Although (I) rearranged in pyridine to yield a thionocarbonate, 1,3-propanediol monoxanthide when treated under similar conditions underwent a different type of rearrangement-fragmentation. This reaction may be represented as follows:

The monoxanthides of 1,4-butanediol, 1,5-pentanediol, and 1,6-hexanediol rearrange similarly to form the *S*-alkyl dithiocarbonate esters in good yield. All the *S*-alkyl dithiocarbonate esters had characteristic absorption maxima at 225 and 280 mμ. A similar spectrum was obtained for the known 1,2 : 5,6-di-*o*-isopropylidene-3-*o*-[(methylthio)-thiocarbonyl]-α-D-glucofuranose. Infra-red analysis revealed nearly identical spectra for the esters with characteristic absorption bands at 7·2 and 8·4μ, whereas the corresponding xanthides had absorption maxima at 7·0 and 8·7μ.

The thermal decomposition of xanthides was reported by Twiss[4] to give *S*-alkyl dithiocarbonate esters along with carbonyl sulphide and elemental sulphur.

Oxidation of Transition Metals in Molten Lithium Chloride–Potassium Chloride Eutectic by Mercuric Chloride

MOST investigations of ionic melts have been concerned with the electrochemical[1] or spectroscopic properties of the solution[2]; relatively little work has been carried out on specific chemical reactions in these media[3,4]. These systems provide obvious advantages over the more conventional liquid media normally used in the preparation of complexes. However, difficulties can occur in isolation of the product from the melts, but these reactions can be particularly useful for the preparation of complexes to be studied *in situ*. As part of the general study of chemical reactions in melts, this communication reports some oxidation studies which we have carried out in potassium chloride–lithium chloride eutectic (40·5 mole per cent potassium chloride) of transition metals, as this provides a useful means of producing a variety of metal chloro-species, some of which are extremely susceptible to hydrolysis. For these complexes the alternative preparations may lead to potential contamination and subsequent difficulty in studying the properties of these compounds in the melt.

From the available redox potentials in the lithium chloride/potassium chloride eutectic, in principle, a number of reactants are capable of oxidizing the transition metals and a preliminary survey using chlorine, mercuric chloride, mercurous chloride and silver chloride was carried out. All the reagents were found to react with a

variety of the metals; thus nickel metal, which is inert to the potassium chloride/lithium chloride eutectic, was rapidly oxidized to the characteristic blue tetrachloronickelate II anion, $[NiCl_4]^{2-}$, by all the reagents. We have confined our investigations chiefly to the mercuric chloride system, as this provides a suitable redox system [$E^\circ = -0{\cdot}5$ V]. In addition, the mercury formed in the reaction was isolated and used as a measure of the oxidation state of the metal ion in solution from the ratio of mercury recovered to metal lost. Using mercuric chloride, it has been possible to oxidize all the transition elements, with the exception of platinum, iridium, osmium and gold, and this technique provides a useful means of rapidly obtaining a solution of these metals which has analytical potential. We have been concerned with establishing both the oxidation state and stereochemistry of the resultant chloro-complexes both in solution and in the solid melts. The oxidation states of manganese, nickel and copper determined chemically are 2·09, 2·07 and 1·01 respectively. The spectra indicate that, in the solid, all the complexes with the exception of cobalt are octahedral, while in the melt iron, cobalt, nickel and possibly manganese are tetrahedral. Thus a change of stereochemistry has occurred on solidification of the melt. The oxidation states of the melts were established as titanium III, chromium III, iron II and cobalt II from the spectra in the melt.

Two sets of conditions can be used, corresponding to an excess of either the metal or the oxidizing agent. In the former case this can lead to a mixture of oxidation states; thus in the vanadium system the spectra and the computed oxidation state ($\sim 2{\cdot}5$) indicate a mixture of vanadium II and III chloro-complexes. It has been shown that vanadium III is reduced to vanadium II by vanadium in the melt[5]. With excess of mercuric chloride only vanadium III species were present. For the second and third row transition elements, it is possible that the intermediate oxidation states obtained may correspond to the formation of metal clusters which formally appear to contain mixed oxidation states[6]; this aspect is at present being investigated as a potential preparative method for these classes of compounds.

BIOPHYSICS

Effect of Temperature on Bioelectric Oscillations of Bean Roots

It has been previously shown that roots of *Vicia faba* immersed in dilute salt solutions generate weak electric fields[1]. These cause potential differences that can be measured in regions adjacent to the root. Under certain conditions, these potentials undergo spontaneous oscillations of several millivolts amplitude, with a period of about 5 min (that is, 12 cycles per hour) at 25° C (ref. 2). If the bioelectric field of a root is not oscillating spontaneously it can be forced to oscillate by subjecting it to periodic oscillations of osmotic pressure, or of concentration of the growth hormone indolyl-3-acetic acid in the surrounding medium. Under these conditions, a characteristic resonance response is observed when the enforcing oscillation has a period close to the natural period of the spontaneous oscillation[3]. This behaviour has been described in terms of a feedback oscillator having three exponential delay elements for which the following sequence of operations has been proposed: the potential of the cellular membrane effects migration of growth hormone electrophoretically; the hormone alters permeability of the membrane, and the resulting change in ion movement modifies the electric field, thus completing the loop. The literature on this subject has been reviewed by Scott[4].

To define more precisely the interacting parts of the feedback loop, we have investigated the effect of temperature on the oscillation of the electric field of the root. This investigation shows that the frequency of the electric oscillation is dependent on the mean temperature of the medium surrounding the bean root.

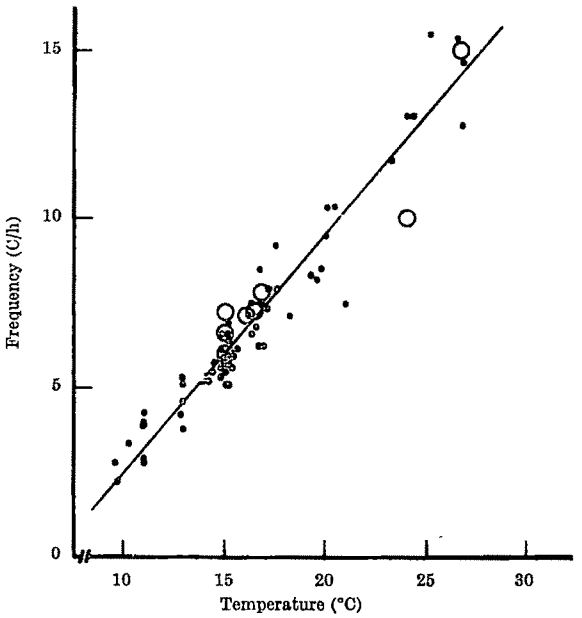

Fig. 1. Frequency of oscillation as a function of mean root temperature. Data obtained for two or more consistent cycles of oscillation. ●, Natural oscillation of twenty-nine roots grown two days at 19°–20° C; ○, resonant response to ± 0·15° C or ± 0·25° C oscillation of temperature.

Fig. 1 gives the average frequency of the natural oscillations of 2 day old roots at various temperatures. Each root was immersed in rapidly flowing 10^{-4} M potassium chloride solution the temperature of which was carefully controlled. Some roots the natural oscillations of which were heavily damped were pre-treated with small amplitude temperature oscillations at the approximate natural period; this reduced damping as described by Jenkinson[5].

The relationship shown in Fig. 1 is significantly linear from 10° C to 27° C (the ordinate of a second order polynomial regression differs by no more than 0·1 per cent from the linear regression to the data). This linearity is unexpected, as many of the processes involved in the postulated feedback loop, and their energy sources, are likely to be thermochemical. In thermochemical reactions one would expect the rate constants to be about proportional to the exponential of $(-E\ddagger/RT)$, where $E\ddagger$, the activation energy, is assumed constant. This relationship approaches an exponentially increasing function over small ranges of temperature variation, and if all three rate constants in the proposed loop varied in this way one would expect the frequency of the loop oscillation to vary with temperature in a similar way. Investigations made into the theoretical behaviour of simple arrangements of the loop components have not yet yielded a model which would have the observed linear frequency relationship. It is likely that more complex processes are involved than described by the simple three-component model—for example, involving non-linear or compensatory elements.

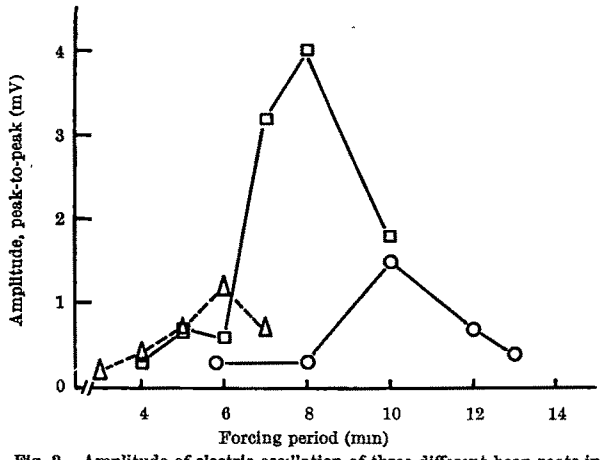

Fig. 2. Amplitude of electric oscillation of three different bean roots in response to ±0·25° C oscillation of temperature at various periods. Mean temperatures: ○, 15° C; □, 17° C; △, 24° C.

The roots also showed a resonant response to changes in the period of small oscillations of the temperature of the bathing medium (see Fig. 2). This behaviour is analogous to that found when osmotic pressure or concentration of indolyl-3-acetic acid is made to oscillate[3]. The amplitude of the applied temperature oscillation was in the range ±0·15° C to ±0·25° C; it was held constant within 0·02° C for each period. The resonant frequencies of some of the beans are shown as open circles in Fig. 1. The resonant frequency corresponds closely to the natural one. This lends further support to the feedback hypothesis, and suggests that the stimulus of small temperature oscillation does not unduly disturb the normal time constants of the feedback loop.

Jenkinson and Scott[3] have shown that the difference in phase between forcing oscillation and bioelectric response provides information on the sequence of operations forming the loop. They have defined the quantity total phase shift as the amount by which this phase difference changes when the period of the forcing oscillation is changed from very short to very long values. The present work has yielded a total phase shift of about 90° C for temperature oscillations. This suggests that the temperature oscillation may be affecting the feedback system at a different point in the loop from that stimulated by oscillation of osmotic pressure (270°) or of indolyl-3-acetic acid (180°).

Future work involves a more detailed investigation of the phase relationships, and of the effect of metabolic inhibitors, with a view to providing a clearer understanding of the nature of the feedback system.

A Possible Explanation for the Effect of Magnetic Fields on Biological Systems

ALTHOUGH there is considerable controversy over the validity of any given example of the influence of a magnetic field on a biological system, the number of such reported phenomena[1] continue to make it a useful task to speculate on mechanisms which are reasonable on a molecular level. The direct influence of magnetic fields on chemical equilibrium or rate of reaction has occasionally been reported; however, this cannot usually be reproduced, and the general weight of evidence is that such effects are insignificant[2]. No satisfactory picture of what a weak magnetic field can do to molecular-level phenomena seems to have been advanced.

To the best of our knowledge the explanation offered here has been overlooked, and appears to offer a consistent and reasoned basis for suggesting that a magnetic field, of the order of 1,000 gauss (G) or more, influences the phenomena of charge transport, both ionic and electronic, mass transport (diffusion rate), and reaction rate in a biological medium. The argument is based on the combination of two rather well-known and well-documented observations: (1) the rod-like molecules in a liquid crystal can orient themselves in a magnetic field; (2) liquid crystalline materials have been identified in a host of biological systems.

Reports on liquid crystals[3] have included several examples of the influence of weak magnetic fields on the orientation of the rod-like molecules and of the consequences of this phenomenon. Forty years ago, using relatively weak magnetic fields (1,000–5,000 G), Svedberg investigated the rates of reactions carried out in mesomorphic states as solvents[4]. He studied the unimolecular thermal decomposition of picric acid, pyrogallol and trinitroresorcinol in *p*-azoxyphenetole, and found that the rate decreased significantly when the liquid crystal was oriented in an external magnetic field. Svedberg also studied rates of diffusion of *m*-nitrophenol in a mixed liquid crystal system of *p*-azoxyanisole and *p*-azoxyphenetole[5]. He found that magnetic fields affected the rate of diffusion—the rate rose when the magnetic fields were parallel to the direction of flow, and fell when the field was applied across the direction of flow.

There have been many reports of the effect of magnetic fields on the dielectric properties of liquid crystals[3]. For example, Maier, Barth and Wiehl[6] found that the difference in the transverse and the longitudinal dielectric constant of 4,4′-di-*p*-methoxyazobenzene increases rapidly up to 1,000 G, and is then independent of field strength. The picture which has developed is that the rod-like molecules, or ellipsoidal swarms of these molecules, are oriented by magnetic fields of the order of 1,000 G and that many of their properties are markedly influenced.

That biological systems are replete with liquid crystalline material has also frequently been reported. For example, Stewart[7] showed that the complex lipids present in the adrenal cortex, ovaries and myelin exist at body temperature in a characteristic mesophase. Robinson[8] has shown a widespread occurrence of the cholesteric phase in polypeptide solutions and biological structures. Reviews of much of this work were presented at the 1965 International Liquid Crystal Conference[9].

This explanation might apply to both "field sensitive" and "gradient sensitive" phenomena[1]. The orientation of rods parallel to a magnetic field occurs for both diamagnetic and paramagnetic materials[10].

Simple Allosteric Model for Membrane Pumps

THE list of plausible hypothetical schemes which have been advanced to account for active transport is so long that any hope of extending it might appear unwarranted. However, very few specific molecular mechanisms have been considered. It therefore appears timely to point out that transport contingent on a chemical reaction can be understood in terms of a very simple molecular model, for which a noteworthy precedent can be found among recent crystal structure determinations.

The proposed pump has some properties in common with earlier proposals of Glynn[1], Burgen[2] and Post[3]. It differs from them in the specific assumption of an allosteric rearrangement as a mechanism for imparting direction to the diffusion process. Its superficial similarity to other proposals[4–8] is outweighed by further reaching dissimilarities.

To function as a pump a polymer molecule must meet three structural conditions only. (1) It must contain a slit or a cavity in the interior of the molecule, large enough to admit a small molecule. (2) It must be able to assume two different configurations, such that the molecular cavity is open to one side of the membrane in one configuration and to the opposite side in the other. (3) It must contain a binding site for the transported species in its molecular cavity, the affinity of which for the transported species is different in the two configurations.

The additional condition that the molecule be oriented within a membrane is not strictly relevant to its ability to function, but is implied, since it must be met if the directional properties of this function are to be observable on a macroscopic scale.

The energy required for the allosteric rearrangement between the two configurations could be derived from any one of many sources. One can conceive of molecular pumps activated electrically, chemically, photochemically, by pressure, and in other ways. The special case of the chemically activated pump is of primary interest here.

The pump is most conveniently discussed in terms of two movable polypeptide chains, shown in Fig. 1, with sodium ion as the transported solute. The number of chains, their exact chemical nature and the nature of the transported species are not critical to the argument.

The two alternative configurations of the pump are represented in Fig. 1, *A* and *B* respectively. The allosteric rearrangement $A \rightarrow B$ results from a chemical reaction, depicted as a phosphorylation of one of the chains, with *A* as the stable form of the unphosphorylated and *B* the stable form of the phosphorylated molecule. The sodium binding site in the molecular cavity has a high affinity for sodium in the *A* form, and a low affinity in the *B* form.

The essential sequence of events in the process of active transport is then the following.

The sodium ion is adsorbed at the binding site in configuration *A* from the left compartment, where the sodium concentration is relatively low. Its adsorption triggers a phosphorylation of the pump (at either a nearby or a distant site); this, in turn, triggers the allosteric rearrangement $A \rightarrow B$, as a result of which the affinity of the binding site for the sodium ion is lowered, the opening to the left compartment closed and that to the right compartment opened. Since the volume of the molecular cavity is small, the sodium concentration within it is in effect larger than in the compartment on the right, providing the chemical potential gradient necessary for diffusion out of the membrane. Dephosphorylation and repetition of the cycle could be triggered either by the outward diffusion of sodium, or by a subsequent adsorption of potassium.

An exceedingly subtle allosteric rearrangement will suffice for the present purpose. A change of 2–3 Å in the relative position of the two chains will determine whether the gate to the molecular cavity is open or closed to a given molecular species. Estimates of the displacements of chemical groups required to alter the affinity of a binding site by one or more orders of magnitude lead to comparable values. Differences of the order of 1–7 Å in the relative positions of haemoglobin chains between crystals of reduced and oxygenated haemoglobin have been found by Muirhead and Perutz[9]. If the current interpretation that these differences result from oxygenation alone is correct, the haemoglobin molecule provides a precedent for the type of molecular mechanism which is required to operate an allosteric pump.

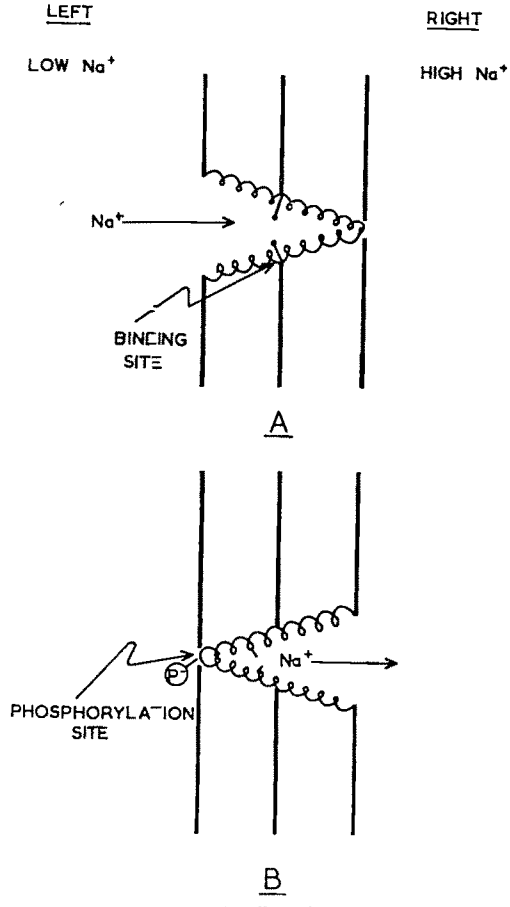

Fig. 1. Longitudinal section of the allosteric pump *A*, Sodium form, *B*, potassium form

Assuming reasonable values for the affinity constant of the binding site and for the dimensions of the molecular cavity, the competence of the allosteric pump is seen to be adequate to sustain most experimentally observed gradients. Thus a pump with three sites for sodium, an affinity constant of the order of 10^3 in the *A* and of the order of 0 in the *B* configuration, and a cavity volume as large as 1000 Å^3, would pump sodium ions from a solution containing 10^{-3} M (or more) sodium into a solution containing 3 M (or less) sodium, either "up" or "down" hill.

Pumps for different molecules need differ only in the specificity of binding sites, and the same pump molecule can be adapted to transport more than one molecular species. Only details of the mechanism need to be altered to account for differences in specificity and for the occurrence of coupled transport. Thus, the stoichiometry of the sodium pump in red blood cells, believed to be an exchange of three sodium for two potassium ions[3,10] for each molecule of ATP, can be accounted for by the scheme shown in Fig. 2.

Each pump unit is thought to consist of three pairs of chains, forming three binding sites specific for sodium in

configuration *A*. Occupation of the middle site triggers the phosphorylation, which, in turn, triggers the molecular rearrangement to *B* and a simultaneous transformation of two of the sites into sites specific for potassium, in the manner shown. Adsorption of potassium triggers the dephosphorylation and rearrangement to *A*, which is accompanied by a loss of affinity for potassium and reappearance of a configuration favourable for a repetition of the cycle.

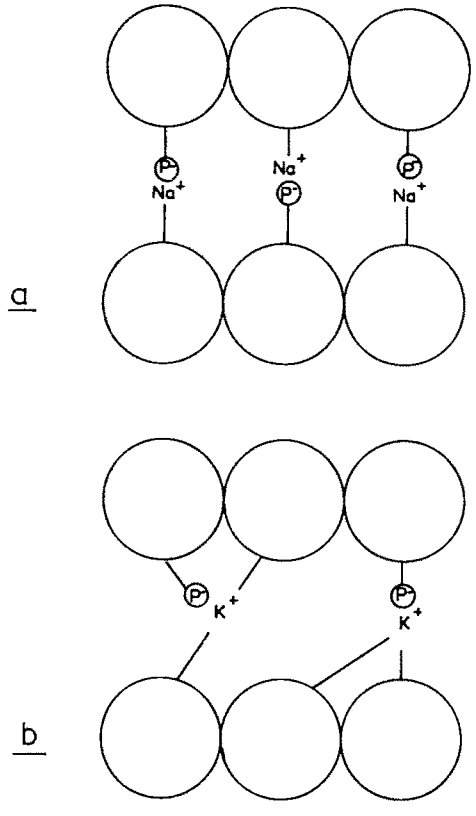

Fig. 2. Transverse section of the coupled sodium-potassium pump *a*, Sodium form; *b*, potassium form.

It should be emphasized that transport by the allosteric pump is in no sense carrier-mediated. Unlike the translocator of Mitchell[4,5] or the rotating carrier of Danielli[11], it requires neither translational nor rotational motion of the binding site. It operates on the same principle as the locks in overland waterways, by altering the potential energy of the transported species. Its kinetics can be described by the diffusion equation applied to a three compartment system (inside/pump/outside), if provision is made for the time-dependence of the intercompartment diffusion coefficients and the chemical potential within the pump. Explicit dependence on the rate of the chemical reaction can be introduced in the conventional manner[12]. The model is not adequately described by a vectorial coupling coefficient, linking the observed flux to the affinity of the chemical reaction[13]. Such a formulation implies complete independence of the rate of transport from the chemical potential gradient across the membrane, which the model clearly does not.

Perhaps the principal virtue of the allosteric model is the simplicity with which it accounts for the principal experimental findings—the ability of very thin (50–100 Å) membranes to concentrate solutes, the localization of the phosphorylation reaction on one side of the membrane[3] and the dependence of pump synthesis on a single genetic locus[14]. In addition it suggests that pump molecules should be amenable not merely to isolation but also to design and synthesis, and that it should be possible to generate reaction-dependent transport in artificial monolayers or crystals formed from them.

BIOCHEMISTRY

Ecological Significance of Anthocyanins in the Seed Coats of the Phaseoleae

THERE is a wide variation in the flavonoids of the seed coat of different cultivars of *Phaseolus vulgaris*[1]. In 'Canadian Wonder', a cultivar which is grown widely both in temperate and tropical zones, we have found the quantities of anthocyanins shown in Table 1. Other cultivars contain these anthocyanins in different proportions, or the compounds may be absent, as in 'Comtesse de Chamborde' for example.

Table 1. APPROXIMATE PERCENTAGE OF WEIGHTS OF ANTHOCYANIN PIGMENT IN DRY SEED-COAT OF 'CANADIAN WONDER'

Flavonoid	Percentage of dry seed-coat
Pelargonidin-3-monoglucoside	1·0
Cyanidin-3-monoglucoside	1·0–1·5
Pelargonidin-3 : 5-diglucoside (P3 : 5g)	0·5 in all: mainly P3 . 5g
Delphinidin-3-monoglucoside	
Cyanidin-3 : 5-diglucoside	

The total quantity of flavonoids may be as high as 5 per cent, but it varies according to the conditions under which the seed is grown and harvested. Because of the variation in the results of investigation of their biological activity, various theories have emerged concerning the part played by the compounds. They were considered to have no, or very little, biostatic activity[2], but this view has recently been revised[3,4]. It would seem that the choice of organism and the test conditions are critical and, in our survey of the activity of sections of paper chromatograms prepared from flavonoid extracts[1] of seed coats, stimulation and inhibition occurred. These tests were carried out by placing 1 cm² chromatogram "cut-outs" on a "lawn" of organisms seeded on Petri dishes. A summary of the results is given in Table 2.

A result of particular interest was the reactivity of pelargonidin-3-glucoside (P-3-G), in view of the high concentration of this compound in the seed coat. Further tests were, therefore, conducted using 0·2 ml. portions of liquid medium in which the spores were suspended, to which P-3-G was added in the form of a chromatographically purified preparation obtained from the original material. These results are presented in Table 3. Organism counts were made using the Miles and Misra technique.

The results show that, at the level of 1,000 p.p.m., P-3-G is biostatic to at least one of the yeasts tested. The observations on bacteria are similar to those of Powers[4], but are not in complete agreement with the hypothesis of Masquelier[3], who suggested that organisms which inhabit soil are less sensitive to inhibition by flavonoids than related pathogenic organisms.

With the *Rhizobium* species, which are known to vary in their output of indolyl-3-acetic acid[5,6], these observa-

tions suggest a possible mechanism for the interaction between host species and symbiont, which determines specificity. It is not suggested that P-3-G is the only, or even the most important, of the flavonoids responsible for this interaction[7], but it is suggested that further investigation of the effects of this group of materials on various species of *Rhizobium* is warranted[8,9].

We consider this type of mechanism is also important in influencing the development of the micro-flora on the leguminous seed-coat[10]; preliminary investigations in this laboratory show that it affects the relations between the groundnut and the toxin-producing species of *Aspergillus*. One reason why its significance has been overlooked is that the width of the inhibition zone around a test spot is not proportional to concentration, in Petri dish tests, as it is with many antibiotics.

We thank Dr. P. S. Nutman (Rothamsted), Miss R. Elliot (Brewing Research Institute) and colleagues at this Institute for the supply of various micro-organisms, and Mr. P. McCoy for technical assistance.

Inhibition of the Biosynthesis of Steviol by a Growth Retardant

THE glycoside stevioside, which occurs naturally in *Stevia rebaudiana* (a South American member of the Compositae), is responsible for the remarkable sweet taste of the leaves of that plant. According to the *Merck Index*, it is 300 times sweeter than sugar. The aglycone of stevioside is the tetracyclic diterpenoic acid steviol. Structurally, it is closely related to gibberellin and shows growth promoting activity in some test plants which were hitherto thought only to be promoted by gibberellin[1–3]. Steviol is also converted by the fungus *Fusarium moniliforme* into a gibberellin-like substance which is apparently not identical with gibberellins A_1–A_9 (ref. 4).

When *F. moniliforme* was grown in the presence of growth retardants such as *AMO*-1618 (2-isopropyl-4-dimethylamino-5-methylphenyl-1-piperidine-carboxylate methyl chloride) or CCC (2-chloroethyl trimethylammonium chloride), less gibberellin was produced, but growth of the mycelia was not retarded[5]. It was concluded that this reduction in the amount of gibberellin produced resulted from inhibition of gibberellin biosynthesis rather than from destruction or inactivation of gibberellin[6]. This conclusion was substantiated by the finding that mevalonic acid, the precursor of gibberellin, was not incorporated into gibberellin by *F. moniliforme* in the presence of *AMO*-1618 (ref. 7). There is good reason to believe that the growth-retarding effect of *AMO*-1618 and CCC in higher plants can be explained in terms of the inhibition of the biosynthesis of gibberellins*. The reduction of the gibberellin content of pea seeds developing in detached pods was reduced by 60 per cent before inhibition of growth became obvious. This clearly indicates that a lowered gibberellin level is the cause rather than the consequence of growth retardation[8]. Using a series of CCC analogues, Harada *et al.* found a complete correlation between the inhibition of gibberellin biosynthesis in *Fusarium* and the suppression of growth in higher plants[9].

We noted that *Stevia* plants treated with *AMO*-1618 failed to exhibit the characteristic sweet taste. By extending this observation and by utilizing the incorporation of acetate into steviol, we were able to show that *AMO*-1618 was indeed responsible for the suppression of the biosynthesis of steviol.

A group of four *S. rebaudiana* plants were treated twice weekly with 16·6 μc. sodium acetate-2-^{14}C dissolved in 0·05 per cent aqueous solution of 'Tween 20'. The solution was applied in 50 μl. drops to the apex and youngest leaves. A total of 250 μc. were administered during the 4 week experimental period. Three of the plants also

* *Note added in proof.* *AMO*-1618 was found to inhibit the cyclization of geranyl-geraniolpyrophosphate in an endosperm preparation from *Echinocystis macrocarpa* (ref. 11).

received 20 ml. of a 4,000 p.p.m. solution of *AMO*-1618 in the form of a soil drench. The growth retardant was also applied twice weekly and for the same period of time as the labelled acetate, but it was applied 1 day before treatment with acetate. The plants were maintained in a controlled environment and subjected daily to 10 h of light at 24° C and to 14 h darkness at 17° C; these conditions applied before and during the experiments. The parts of the plant that formed after the application of the chemicals were separated from the older parts and lyophilized, extracted and hydrolysed according to a previously described procedure[10].

Ninety-three milligrams of residue were obtained from the *AMO*-treated plants and 37 mg from control plants (no *AMO*): 1·86 mg of the former and 1·91 mg of the latter were spotted as 2 cm wide strips 15 mm from the edge on a 50 × 200 × 0·25 mm layer of silica gel *H* (Brinkmann Instr.). These were then developed over 170 mm in $CHCl_3$–EtOAc–HOAc (12 : 8 : 1), and scanned for radioactivity in an adapted Actigraph II (Nuclear Chicago). The results, as shown in Fig. 1, indicated that the radioactivity associated with steviol from the *AMO*-treated plants was about half that of the controls. The fluorescence of steviol under ultra-violet light after charring the thin-layer chromatogram with 50 per cent sulphuric acid on a hot plate also indicated that less steviol was present after treatment with *AMO*.

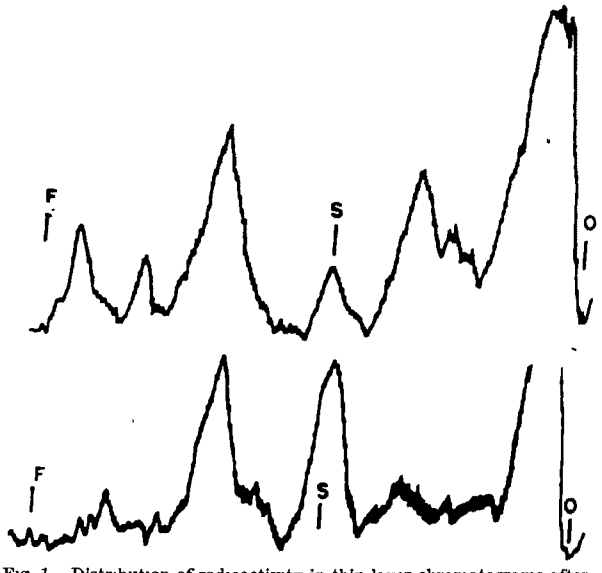

Fig. 1. Distribution of radioactivity in thin-layer chromatograms after treatment of *S. rebaudiana* with radioactive acetate. Upper curve: plants received *AMO*–1618. Lower curve: control, no *AMO*. Chromatogram scanned at 0·75 in./h, full-scale 300 c.p.m., time constant 40 sec, slit width 0·0625 in. *S*, Steviol, as shown by means of co-chromatographing a sample of authentic steviol, and also demonstrated in earlier work (ref. 4) by chemical means (crystallization to constant specific activity, melting point, and preparation of a derivative).

As in other plants, treatment with *AMO* causes a reduction in internode length in *S. rebaudiana*. Gibberellic acid completely counteracted the growth retardation; however, the lowered contents of steviol appeared not to be affected. The results suggest that *AMO* interferes not only with the biosynthesis of gibberellin, but also with that of the cyclic diterpenes in general. These findings are significant in two respects. *AMO*, and perhaps also other growth retardants, can be used for blocking the synthesis of certain plant terpenes and can thus serve as a tool to elucidate further the biosynthetic pathways. Furthermore, cyclic diterpenes can be used as "model substances" for studying certain parts of the biosynthesis of gibberellins in higher plants. This is of considerable interest because the gibberellin content of most higher plants, except certain seeds, is very low, which renders the isolation and identification of intermediates a difficult task. In contrast, the level of diterpenes in some plants is quite high. Stevioside amounts to as much as 7 per cent of the dry weight of *Stevia rebaudiana* plants.

The steviol biosynthesis was not completely suppressed, even though a high concentration of *AMO* was used. This could have resulted from the fact that separation of the parts formed after the commencement of the *AMO* treatment from those which had been present before was not complete. Another reason could be that 24 h between *AMO* and the application of acetate was not sufficient time to allow adequate amounts of *AMO* to be translocated to the biosynthetic sites of steviol, which are apparently the youngest leaves.

I thank Prof. A. Lang for stimulating discussions on this subject. The work was supported by a grant from the National Science Foundation.

Ribonucleic Acid Turnover in Tobacco Leaves infected with Tobacco Mosaic Virus

A LARGE number of investigations using different techniques have shown that the nucleus and the chloroplasts of infected leaf cells are implicated in the synthesis of tobacco mosaic virus (TMV). The source of materials for the synthesis of virus protein and ribonucleic acid (RNA) has been shown to be low molecular weight residues which are in metabolic sequence with carbon dioxide, ammonia and inorganic phosphate[1]. Recently, however, Reddi[2] reported that the uridine, but not the phosphate, component of TMV–RNA was derived from the degradation of ribosomal RNA, which occurred as a result of infection. This communication describes some results of a study of the effect of TMV synthesis on the RNA content and turnover of mainly two fractions of tobacco leaves. Half-leaves of *Nicotiana tabacum* var. White Burley, about 20 cm long, were inoculated with TMV, the opposite leaves serving as control, except when the sampling was to continue for more than three days after inoculation when separate plants were used. Leaves were sampled by taking leaf pieces of equal wet weight for each sample in such a way that each part of the leaf was represented in each sample. Incubation of the leaf pieces in phosphorus-32 was achieved by infiltrating them with 1–5 μc./ml. of carrier-free phosphorus-32 in distilled water at *p*H 6·5, and leaving them at 23·5° C under illumination. The leaf tissue was ground in 25 mM *tris*-hydrochloric acid at *p*H 7·6, containing 5 mM magnesium chloride, 1 mM calcium chloride, 0·5 M sucrose, and 10 mM β-mercaptoethanol at 0°–4° C. Debris was removed by centrifugation at 100*g* for 30 sec. The supernatant was fractionated into a nuclear-chloroplast fraction (2,000*g* for 5 min), containing also starch grains and some cell wall material; a mitochondrial fraction (42,000*g* for 12 min), containing also cell membranes, some green material and, in the case of infected leaves, some virus; and a ribosomal fraction (140,000*g* for 90 min) containing ribosomes and the remaining virus. Ribosomes and virus were separated by dissolving the ribosomal pellet in 0·3 ml.

tris buffer, 25 mM, at *p*H 7·6, containing 5 mM magnesium chloride, and centrifuging the solution at 120,000*g* for 70 min on a 5–20 per cent sucrose density gradient column prepared in 25 mM *tris* buffer containing 5 mM magnesium chloride. The column was sampled by collecting drops; the drops constituting the ribosomal zone were pooled and the concentration determined by spectrophotometry. RNA was extracted with phenol and an equal volume of 25 mM *tris* buffer at *p*H 7·6 by shaking in the cold for 10 min. The water phase was re-extracted with phenol and excess phenol was removed with two ether extractions. Ribonucleic acid was precipitated with three volumes of ethanol and three drops of 3 M sodium acetate overnight at −17° C, and the precipitate was dissolved in distilled water. Precipitation with ethanol was repeated twice. When RNA free of radioactive impurities was required, the ethanol precipitations were followed by three cycles of solution in 6 M guanidine chloride and 10 mM ethylenediamine tetraacetic acid at *p*H 7·2 and precipitation with 1·2 volumes ethanol in the cold. Finally, the RNA was washed with 70 per cent ethanol, defatted, and hydrolysed in 0·2 ml. 1 N potassium hydroxide at 30° C for 16 h. The hydrolysate was adjusted to *p*H 3·5 with perchloric acid, and the nucleotides were separated by high voltage electrophoresis in 50 mM potassium citrate buffer at *p*H 3·50. Radioactivity was counted using a liquid scintillator in a 'Packard Tricarb' spectrometer.

The RNA content per unit area of the leaf fractions decreased with leaf expansion. The ribosomal RNA decreased faster than all other fractions, but there was no difference in the rate of degradation between infected and control leaves of plants grown under three different growth conditions. The mitochondrial fraction of the infected leaves exhibited a less pronounced rate of degradation, because some TMV sedimented with this fraction. In accord with other findings[3], the nuclear-chloroplast (N–C) fraction of infected leaves 2–3 days after inoculation showed a small (about 15 per cent) increase relative to control leaves, which corresponded to a third of the RNA incorporated in whole virus at that time. Attempts were made to find whether this RNA was in any way connected with the synthesis of TMV–RNA. Incubation of leaf tissue with phosphorus-32 followed by fractionation showed that the specific activity of the N–C fraction, not unexpectedly, was eight times higher than that of the ribosomes. Incorporation of phosphorus-32 by the N–C fraction of the infected leaves increased continuously with incubation time, whereas the same fraction of the control leaves reached a plateau after about 80 min (Fig. 1). The stimulation of RNA synthesis after 120 min was usually 40 per cent. After 4 h of incubation stimulation was apparent. The incorporation of phosphorus-32 by ribosomes showed a similar increase beginning after 90 min, but it was less evident after shorter incubation times, and varied between 10 and 30 per cent (Fig. 2).

Extraction of the RNA of the N–C fraction with phenol left about 10 per cent of the RNA unextracted. This was extracted by adding sodium dodecyl sulphate at a final concentration of 0·3 per cent to the phenol phase and extracting the RNA using *tris* buffer at *p*H 7·6 for 15 min at 50° C. The specific activity of the sodium dodecyl sulphate–RNA was three times higher than that of the phenol RNA, but there was no difference in specific activity between those of infected and control leaves irrespective of incubation time.

Determination of the nucleotide composition of the RNA of the N–C fraction, obtained from the relative radioactivity of the nucleotides, did not indicate that TMV–RNA (cytidine monophosphate (CMP) 19·4, adenosine monophosphate (AMP) 29·1, guanosine monophosphate (GMP) 24·4, uridine monophosphate (UMP) 27·1), or its complementary strand[4], was involved. The shift of composition of this fraction towards high AMP and UMP content (CMP 21·2, AMP 26·2, GMP 29·4, UMP 23·2), compared with the composition derived from spectrophotometric methods (CMP 22·3, AMP 23·0, GMP 31·9, UMP 22·7), and the variability of determinations in different experiments possibly obliterated any real difference. The composition of the ribosomal RNA was more consistent (CMP 21·8, AMP 24·9, GMP 30·3, UMP 23·0), but there was no significant difference between infected and control leaves.

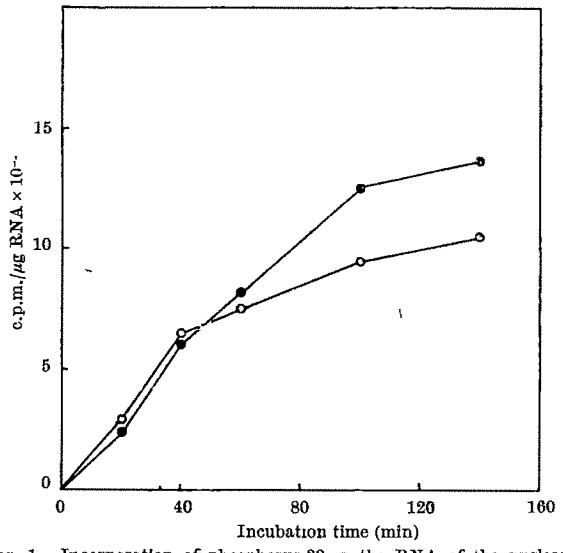

Fig 1. Incorporation of phosphorus-32 in the RNA of the nuclear-chloroplast fraction of healthy and TMV infected tobacco leaf cells ●, Infected; ○, healthy.

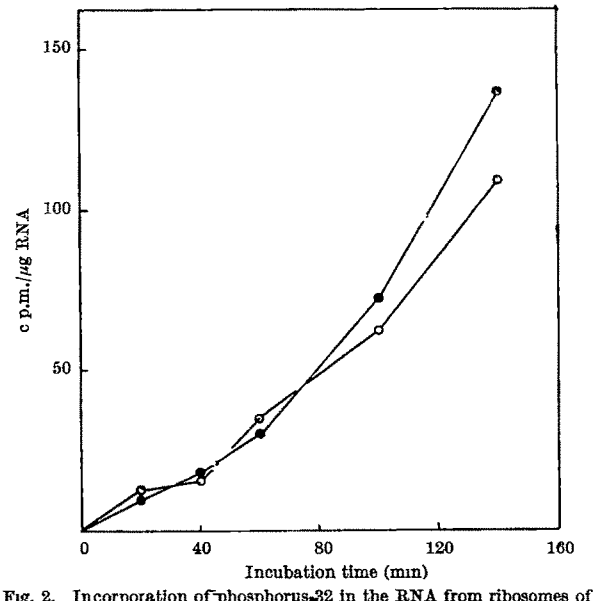

Fig. 2. Incorporation of phosphorus-32 in the RNA from ribosomes of healthy and TMV infected tobacco leaf cells. ●, Infected; ○, healthy.

It was concluded that infection of tobacco leaves with TMV stimulates synthesis of RNA in the nuclear-chloroplast fraction, which may be responsible for the increased incorporation of phosphorus-32. It can easily be extracted, which suggests that it is not firmly bound to any cell component. The nucleotide composition did not reveal similarity to TMV–RNA. The higher specific activity of the RNA from ribosomes of infected leaves only after long periods of incubation time suggests that the extra radioactivity is not incorporated into the ribosomal RNA, but into an extraneous RNA bound to ribosomes. This

RNA may participate in the production of some protein necessary in virus multiplication.

Porphyria induced in Rats by Orotic Acid and the Effect of Adenine-5′-monophosphoric Acid

IN previous work we showed that adenine nucleosides and nucleotides play an important part in the quantitative regulation of porphyrin biosynthesis. Administration of inosine or adenosine monophosphate (AMP) reduced significantly the excess porphyrin formation in rats caused by different toxic agents (for example, allylisopropylacetylcarbamide, hexachlorobenzene, 3,5-dicarbethoxy-1,4-dihydrocollidine, lead acetate and griseofulvin)[1–3]. On the other hand, porphyrin synthesis by illuminated suspensions of *Rhodopseudomonas spheroides* in Lascelles medium I was strongly inhibited by AMP, adenosine diphosphate (ADP) and adenosine triphosphate (ATP). ATP was found to provoke more than 90 per cent inhibition at a concentration of 3 mM.

These observations have led us to study the reverse problem, namely, the effect of the decrease in the biosynthesis of ATP on porphyrin formation. Orotic acid seemed to be particularly suitable for this purpose, as it was recently shown by Von Euler *et al.*[5] that a balanced diet containing 1 per cent orotic acid caused a 50 per cent decrease in the hepatic level of acidosoluble nucleotides in rats.

Our experiments with rats maintained for 1–3 weeks on the diet used by Von Euler *et al.* confirmed these findings. Using the luciferase method[6] we found a highly significant reduction in the level of hepatic ATP. Unexpectedly, a similarly significant increase was observed in the concentration of ATP in the red blood cells. At the same time, we noted significant hepatic steatosis (Table 1).

Table 1

	Rats intoxicated by orotic acid during 3 weeks	Controls	Rats intoxicated by orotic acid during 1 week
Liver ATP level (μmol/100 g net weight)	60 ± 8·7 (mean of 10 rats) $t = 4·6$ $P < 0·001$	164·5 ± 11·0 (mean of 10 rats)	98 ± 10·7 (mean of 8 rats) $t = 3·03$ $P < 0·01$
Erythrocytic ATP level (μmol/100 ml.)	83 ± 8·5 (mean of 9 rats) $t = 7·7$ $P < 0·001$	46 ± 1·6 (mean of 11 rats)	89 ± 7·1 (mean of 8 rats) $t = 7·5$ $P < 0·001$
Total liver lipids (g/100 g net weight)	8·4 ± 1·2 (mean of 8 rats) $t = 3·6$ $P < 0·01$	3·8 ± 0·23 (mean of 10 rats)	— —

In order to study the ensuing disturbances of porphyrin metabolism, three series of experiments were followed, namely, administration of the diet containing 1 per cent orotic acid for 1, 2 and 3 weeks. Urinary and faecal porphyrins and porphyrin precursors, δ-aminolaevulic acid and porphobilinogen (ALA and PBG) were studied every 3–4 days. The level of etherosoluble porphyrins (copro + protoporphyrin) in the liver and red blood cells was determined immediately after death provoked by bleeding following mild ether anaesthesia. After 2 weeks of orotic acid administration, we also studied the level of etherosoluble porphyrins in the pooled bone marrow of eight rats and the activity of ALA synthetase in mitochondria isolated from the liver of four rats, using the method of Granick and Urata[7].

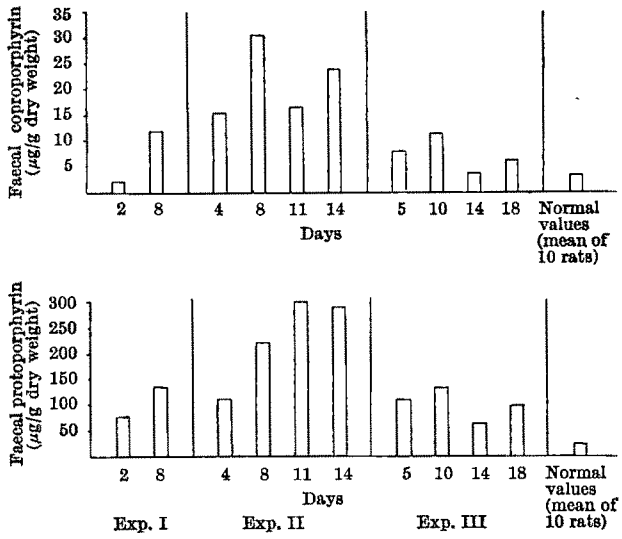

Fig. 1. Balanced diet containing 1 per cent orotic acid maintained for: 1 week (Exp. I); 2 weeks (Exp II); 3 weeks (Exp. III).

The urinary excretion of porphyrins and porphyrin precursors remained at almost normal levels between practically normal limits in all our experiments. On the other hand, there was a very marked increase in faecal porphyrin excretion (Fig. 1). There was a similar increase in the concentration of etherosoluble porphyrins in the liver and red blood cells when orotic acid was administered for at least 1 week, and furthermore, a significantly high level of these porphyrins was found in the bone marrow. After two weeks' intoxication with orotic acid enhanced activity of ALA synthetase was discovered in liver mitochondria (Table 2).

Table 2

	Rats intoxicated by orotic acid for 2 weeks	Controls	Rats intoxicated by orotic acid for 1 week
Hepatic level of etherosoluble porphyrins (μg/100 g net weight)	16·2 ± 0·9 (mean of 8 rats) $t = 4·0$ $P < 0·01$	8·4 ± 1·4 (mean of 6 rats)	12·4 ± 0·4 (mean of 9 rats) $t = 2·3$ $P < 0·05$
Erythrocytic level of etherosoluble porphyrin (μg/100 ml.)	69·0 ± 3·5 (mean of 8 rats) $t = 5·6$ $P < 0·001$	50·6 ± 1·95 (mean of 10 rats)	78·0 ± 3·3 (mean of 9 rats) $t = 6·4$ $P < 0·001$
Etherosoluble porphyrins in pooled bone marrow (μg/10^{10} red cells)	38 (mean of 8 rats) —	23 (mean of 8 rats)	— —
ALA synthetase activity in liver mitochondria (mμmol ALA formed / mg protein of mitochondria)	19·8 ± 3·5 (mean of 4 rats) —	0–4·5 (mean of 10 rats)	—

Our findings show that the administration of orotic acid to rats provokes a highly significant increase in the faecal, erythrocytic and medullary level of etherosoluble porphyrins and only a mild increase in the liver concentration of these pigments. As the urinary excretion of porphyrins and porphyrin precursors was virtually unmodified, the observed disturbances of porphyrin metabolism appear to be similar to those found in human erythropoietic protoporphyria[8].

The increased activity of ALA synthetase in liver mitochondria of rats intoxicated with orotic acid suggests that the accumulation of porphyrins can be attributed to the stimulation of their synthesis by the toxic agent. Granick has shown this to be so for other compounds capable of inducing experimental porphyria[9].

Thus we now have some evidence that the enhancement of the porphyrin biosynthesis by orotic acid is related to a decrease in the formation of ATP by the liver. Intramuscular administration of AMP at the dose of 20 mg per rat per day from the beginning of the period of intoxication with orotic acid was found to reduce very significantly

excess porphyrin formation as well as the increased ALA synthetase activity of liver mitochondria (Table 3).

Table 3

	Intoxication with orotic acid for 2 weeks	
	Rats treated with AMP (8 rats)	Rats not treated with AMP (8 rats)
Faecal etherosoluble porphyrins 4th day	106·5	124·7
(μg/g dry weight) 8th day	216·7	252·5
11th day	259·5	320·0
14th day	257·5	313 0
Etherosoluble porphyrins in liver tissue (μg/100 ml. net weight)	11·6 ± 0·7 $t = 5·2$	16·2 ± 0 9 $P < 0$ 001
Etherosoluble porphyrins in red blood cells (μg/100 ml.)	43 ± 1·7 $t = 6·0$	69·0 ± 354 $P < 0$ 01
Etherosoluble porphyrins in pooled bone marrow (μg/10^6 erythroblasts)	26	38
ALA synthetase activity in liver mitochondria (mμmol ALA formed per mg protein of the mitochondria preparation)	19 8 ± 3·5 $t = 3·1$	35·8 ± 4·1 $P < 0$ 02

These results confirm our earlier observations concerning the experimental production of porphyria by a toxic adenine analogue, 6-mercaptopurine. This compound was also found to reduce the biosynthesis of ATP. The metabolic disorders of this porphyria were significantly alleviated by the administration of inosine[10].

An experimentally induced porphyria was observed in mice following the administration of griseofulvin (by de Matteis and Rimington[11]), and in rats (by ourselves[3]). MacNall[12] has emphasized the structural similarity of griseofulvin with the purine ribosides and suggests that this antibiotic may act as a competitive analogue. In this connexion, it is interesting that we found that the administration of AMP or inosine improved the disturbances of porphyrin metabolism induced by griseofulvin in rats[3].

Gonadotrophin-inhibiting Action of Certain Carbohydrates

A GONADOTROPHIN-INHIBITING substance has been reported to occur in the urine of children[1] and adults[2,3] and in certain samples of human serum[4]. It inhibits the action of human chorionic gonadotrophins (HCG) and luteinizing hormone (LH), but is ineffective against the action of follicle-stimulating hormone (FSH). This communication reports the observation of certain similar effects using *N*-acetyl-D-neuraminic acid (D-NANA)—a constituent of both HCG and FSH, and using the related compound *N*-acetyl-D-mannosamine (D-NAM).

Synthetic D-NANA was obtained from the Koch-Light laboratories and related compounds were synthesized in this Department. Before they were injected into animals, these compounds were dissolved in water and carefully neutralized with dilute sodium hydroxide if necessary. The uterine weight assay[5] and the ovulation assay[6] were carried out using immature mice.

In a typical experiment, D-NANA and HCG were mixed in the proportion of 1 mg to 1 I.U. The regression of the log response on the log dose was significant, and in a three by two assay the potency of the mixture was only 39 per cent (95 per cent fiducial limit 14–67) compared with that of HCG alone.

The effect of D-NANA was also investigated using proportions of 1 mg to 3 I.U. HCG and 1 mg to 32 I.U. HCG with dosages ranging from 0·5 I.U. to 16 I.U. HCG. There was some reduction of uterine weight in mice given the first mixture, but when the uterine weights of animals given a higher proportion of HCG to D-NANA were determined, no significant reduction was found. The compound *N*-acetyl-D-mannosamine was also tested; it is biochemically related to D-NANA by means of a reversible aldolase reaction involving pyruvic acid and alternative pathways[7]. When mixed in the proportion of 1 mg to 1 I.U. HCG, it reduced the mean uterine weight to 62 (48–80) per cent of the mean uterine weight of mice given the same doses of HCG alone. With respect to HCG it was also effective when given at twice this dosage. The inhibitory action seems to be relatively specific as the isomeric compound *N*-acetyl-D-glucosamine was without significant effect (uterine weights 88 (62–124) per cent of the controls). Furthermore, L-NANA, *N*-acetyl-L-mannosamine and fourteen other closely related derivatives were inert.

This assay is not specific for HCG. For this reason the effects of D-NANA and other compounds were investigated in the ovulation test in mice[6] which is relatively specific for HCG and LH. Both D-NANA and D-NAM reduced the activity of HCG in this test. When mixed in the proportion of 1 mg to 1 I.U. HCG the potencies (compared with controls in 2 : 2 assays) were 68·9 (13·3–106) per cent for D-NANA, and 61 (42–96) per cent for D-NAM. These results extend and confirm the preliminary observations of Ladman and Soper[8], who used a similar assay technique but who had only a very crude preparation of NANA. They found that increasing dosages of this material progressively decreased the number of ova produced in mice given 0·5 I.U. HCG. Some toxicity was noted at the highest dose used (50 mg). It is probable that this resulted from impurities in the preparation, or from the *p*H of the final solution which was not recorded. During the course of our work we have not noted any toxic effects when D-NANA has been administered in neutral solution. Finally, neither D-NANA nor D-NAM was found to have any effect on the uterine-stimulating activity of oestradiol-17β, or on human pituitary LH as determined by the ovulation assay (relative potency 100 (66–152) per cent). The latter observation is surprising in view of the close similarity between the biological activities of LH and HCG. However, it is known that pituitary LH differs chemically from HCG as it does not contain appreciable amounts of NANA and does not suffer loss of activity on incubation with neuraminidase[9].

The action of hormones depends on their structure and their ability to reach their target cells. It is tempting to suggest that any entity which inhibits the action of HCG is concerned with one or more of the following features: (i) an ability to compete for a site of hormone action (compare with the well known haemagglutination phenomena of the influenza virus where NANA-containing mucoproteins and polysaccharides are competitive inhibitors[10]); (ii) an ability to undergo conversion into a compound exhibiting (i). These features may be operative in the inhibition of HCG activity by D-NANA and D-NAM and they appear all the more significant when it is appreciated that human pituitary LH is not inhibited in the same way.

This work was carried out under a block grant from the Medical Research Council, with additional support from the National Research Development Corporation. We thank Prof. M. Stacey for his encouragement and interest throughout this work, Dr. M. J. How and Dr. R. G. Plevey for the numerous derivatives, Mr. P. Bertrand for the statistical analyses and Mr. D. Whyman for his assistance with the bio-assays.

Administration of *N*-Acetyl-D-mannosamine to Mammals

N-ACETYL-D-mannosamine (NAM) is biochemically related to *N*-acetyl-D-neuraminic acid (NANA), a constituent of both human follicle stimulating hormone and human chorionic gonadotrophin (HCG). The compound itself is devoid of biological activity, but when mixed with HCG it reduces the activity of this hormone in both the uterine weight and ovulation assays[1]. We therefore considered it to be of interest to study the fate of NAM after the administration of it to mammals.

N-Acetyl-D-mannosamine has a pleasant, bland, sweetish taste. It has not been found free in human serum but has been reported to occur in human semen[2]. In mammals it is interconvertible with its 6-phosphate[3] and with NANA[4] by way of condensation with pyruvate. It can be assayed in aqueous solution using the Morgan-Elson reagents[5].

In determining NAM in plasma (3–150 μg/ml.) it has been found preferable to dialyse the plasma (1 ml.) against water (100 ml.) at 2° C overnight and then to pass the dialysate down a 'Dowex 50H+' column (30 × 1·5 cm). The first 150 ml. which was collected was freeze-dried, redissolved in water (1·2 ml.) and the NAM estimated on a suitable portion (1 ml.). The method was calibrated by adding known amounts of NAM to samples of serum and submitting them to the same procedure and reading the optical densities against a serum blank.

After oral administration of NAM to human subjects, the levels detected in serum were extremely variable. There are several possible reasons for this; one important factor appeared to be the relative blood glucose level while another was the presence of bacteria in the saliva which synthesized induced enzymes capable of destroying NAM[6].

The maximum levels of NAM which could be detected in five starving subjects were 78 μg/ml. (4 h after 5 g NAM), 205 μg/ml. (1 h after 5 g NAM), 104 μg/ml. (4 h after 10 g NAM), 20·8 μg/ml. (8 h after 10 g NAM), while in the fifth no NAM was detectable in the serum up to 8 h after 10 g NAM had been administered. A sixth subject took ampicillin (1·5 g) during the previous 36 h to destroy possible salivary bacteria and showed a maximum serum level of 30 μg NAM/ml. 4·5 h after taking 10 g. No NAM could be detected in the urine of two subjects given 5 g and 10 g oral doses of NAM. In the subject with the highest level of NAM (205 μg/ml.) the concentration had dropped to 10 μg/ml. in a further 2·75 h. During this time there was also a fall in blood glucose from 69 mg/ml. to 49 mg/ml. The blood glucose (75 mg/ml.) was determined in the third subject when the level of NAM was 104 μg/ml. After a midday meal, the level of NAM slowly fell to 78 μg/ml. after a period of 1·5 h while the blood glucose rose to 100 mg/ml. 1·5 h later the level of NAM was still 72·2 μg/ml. and the blood glucose 88 mg/ml.

It would appear that much of the NAM administered orally is converted to glucose as there is a rapid rise in blood glucose in the starving subjects. Thus administration of 10 g NAM to one subject caused a rise in the blood glucose from 76 mg/ml. at 1 h to 108 mg/ml. at 4 h, while in a second it rose from 51 mg/ml. at 0·5 h to 100 mg/ml. at 1 h. In two subjects, when NAM (10 g) was administered 30 min after 10 g glucose had been given, extremely low levels of NAM resulted, the maximum after 4 h being only 16·6 μg/ml. Oral administration of NAM (10 g) to two other subjects 2 h after breakfast resulted in similar low levels of NAM, the maximum after 4 h being 11 μg/ml. and 14·6 μg/ml. of NAM respectively.

Tablets of NAM (5 g) taken sublingually over 15 min were ineffective in one subject who was later found to have salivary bacteria active against NAM. Enteric coated (cellulose phthalate acetate) NAM (5 g) swallowed by the same subject produced a NAM level of 56 μg/ml. after 5 h while in a second subject who took 2·5 g the serum level of NAM rose to 30 μg/ml. after 8 h.

Parallel experiments were performed in sheep. Two sheep given 1 g NAM intravenously rapidly metabolized it giving serum levels of 43 and 47 μg/ml. (0·75 h), 25, 33 (1·5 h), 6, 7 (4·5 h), 5, 12 (6 h) and 9, 4 (24 h). In the first animal the serum level at 0·25 h had reached 72 μg/ml. Rather similar results were obtained in two sheep given 1 g NANA intravenously and serum levels were 53, 79 μg NANA/ml. (0·25 h), 38, 24 (0·75 h), 21, 21 (1·5 h) and 7, 8 (4·5 h).

Portions (39·4 mg) of (*N*-acetyl-1-^{14}C)-D-mannosamine (0·269 g) were prepared[7] by treatment of D-mannosamine hydrochloride (0·4 g) with (acetic-1-^{14}C) anhydride (0·2 mc.) dissolved in acetic anhydride (0·25 ml.). These were injected into two female rats. One rat was dissected after 1 h and the other after 3 h. The extraction of the test compound from each organ was carried out overnight at room temperature. Five millilitres of acetone were used for all organs except for the liver, which required 10 ml. and small organs (pituitary, gut, heart, ovaries, uterus, thyroid) which were given 2 ml. only. Thereafter all organs were extracted three times with acetone (5 ml.). The dry weights of the organ residues were determined. The activity of each extract was determined with a Packard 'Tricarb' liquid scintillation counter and expressed as total 100 sec count of bulked acetone extracts/mg dry weight. The major site of radioactivity was the kidneys (528 after 1 h; 62 after 3 h) rather than the liver (85 after 1 h; 28 after 3 h) or spleen (54 after 1 h; 11 after 3 h). Epithelial tissues were richer in activity (skin, 207, 29; gut, 174, 35; lung, 208, 17) than muscle (67, 13), heart (110, 13) or brain (20, 9). The ovaries (159, 39) and uterus (144, 47) were also noticeably active in contrast to adipose tissue (77, 21) with its slow rate of turnover. Activity rapidly disappeared from the blood; some was recovered in the urine and faeces, but the major amount of NAM was presumably metabolized by way of the Krebs cycle.

We thank Mr. L. E. Rowson, Agricultural Research Council Unit of Reproduction and Physiology, Cambridge,

for injecting the sheep and Mr. Stevenson for enteric coating the NAM tablets.

Experimental Porphyria induced in Rats by Ethionine

Our earlier findings have shown that administration of adenine nucleosides or nucleotides to rats with different experimental porphyrias was followed by a decrease in excess porphyrin formation[1-4]. These observations have led us to the conclusion that these purine derivatives and particularly ATP play an important part in the quantitative regulation of porphyrin biosynthesis[1]. Moreover, it occurred to us that if this hypothesis is correct, administration of compounds capable of causing a decrease in the biosynthesis of adenosine triphosphate (ATP) might well bring about the formation of excess porphyrins and porphyrin precursors. Our observations with 6-mercaptopurine[3] and orotic acid[4] have confirmed this working hypothesis.

Ethionine seemed to be a particularly interesting compound in this respect, as several authors have already shown that ethionine is a powerful inhibitor of hepatic ATP synthesis, even after a single dose[5-7]. On the other hand, Gibson *et al.*[8] have reported that ethionine stimulates porphyrin synthesis in *Rhodopseudomonas spheroides*.

We have therefore made this investigation of the effect of ethionine on porphyrin metabolism and the level of ATP in the liver and red blood cells of the rat. Three different types of experimental condition were set up: (1) The rats were maintained on a low protein diet (8 per cent casein containing 0·5 per cent ethionine) for 3 weeks. (2) Another group of rats received a daily dose of 50 mg ethionine (administered by gastric tube) for 1 week. The diet of these animals contained 12 per cent casein. (3) A third group of animals received 100 mg ethionine per day (administered by gastric tube) for two successive days. These rats were maintained on a balanced diet.

Controls were fed the same diet as the rats treated with ethionine. Whenever ethionine was introduced through the gastric tube, the controls received a corresponding volume of solvent (physiological saline) by the same means.

Urinary and faecal porphyrins and porphyrin precursors (ALA and PBG) were determined every 3–4 days. The level of etherosoluble porphyrins (coproporphyrin + protoporphyrin) was determined in the liver and red blood cells immediately after death provoked by bleeding following mild ether-anaesthesia. Where ethionine had been administered for 2 days only, a porphyrin analysis of the red blood cells was omitted. The luciferase method[9] was used for the determination of ATP levels in liver and red blood cells. In some animals, the activity of ALA-synthetase in liver mitochondria was also determined, using the method devised by Granick and Urata[10]. In order to test the effect of adenine nucleosides or nucleotides on the disturbances of porphyrin metabolism, brought about by ethionine, inosine or adenosine monophosphate (AMP) or ATP was administered intramuscularly at a daily dose of 20 mg from the beginning of the period of ethionine intoxication.

Urine analyses showed a clear-cut increase in ALA and coproporphyrin excretion in rats intoxicated with ethionine. This increase was important even in our shortest experiments (2 days). Porphobilinogen appeared in the urine of some rats only during the first days of ethionine administration and uroporphyrin was not detected (Fig. 1). Our findings concerning the faecal excretion of copro- and proto-porphyrin were somewhat complicated by the side effects which resulted from administration of a low protein diet. In our first and second series of experiments (diets containing, respectively, 8 per cent and 12 per cent casein), the intestinal excretion of porphyrins was very significantly increased even in the control. Nevertheless, during the first week of ethionine administration, the increase was clearly higher in the intoxicated rats than in the controls. In the short experiments (2 days) where the animals were maintained on a balanced diet, the stimulating effect of ethionine on the accumulation of faecal porphyrins was fairly evident (Fig. 2).

As is shown in Table 1, the level of etherosoluble porphyrins in the liver and red blood cells was found to be significantly increased except in rats of the first experimental series, where ethionine had been administered for 3 weeks. This last fact, together with the decline in the level of faecal porphyrins in these animals during the last week of the experimental period, can probably be attributed to a general inhibition of biosynthetic processes provoked by the prolonged ethionine intoxication. We noted, just as Hutterer *et al.*[11] had, that at the end of the longer experiments there was no significant difference in

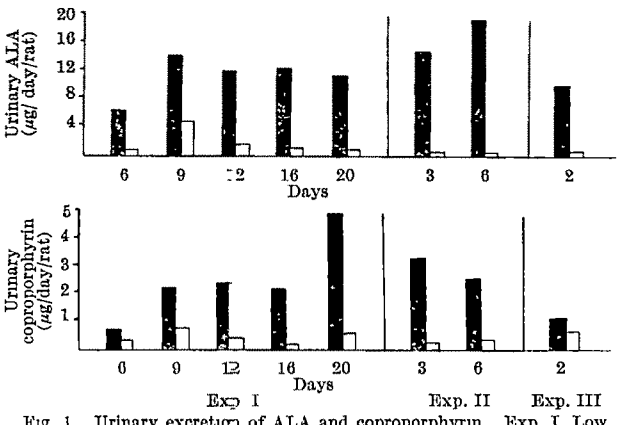

Fig. 1. Urinary excretion of ALA and coproporphyrin. Exp. I, Low protein diet (8 per cent casein) containing 0·5 per cent ethionine for 3 weeks. Mean value of six intoxicated and six control rats. Exp II, Low protein diet (12 per cent casein), 50 mg ethionine daily by gastric tube for 1 week. Means of twelve intoxicated and twelve control rats. Exp. Fig 2. ■, Rats intoxicated by ethionine; □, controls.

the lipid content of the liver between ethionine-treated and control rats. However, we observed a decrease in the level of hepatic ATP after administration of ethionine for 1 week or 2 days; the concentration of ATP in the red blood cells remained unchanged (Table 2). No increase was observed in the activity of ALA-synthetase in the liver of mitochondria of rats intoxicated with ethionine for 3 weeks. Administration of inosine, or AMP or ATP, did not appear to have any effect on the disturbance of porphyrin metabolism caused by ethionine.

Thus our findings clearly show that ethionine intoxication for 3 weeks, 7 days or even 2 days causes a statistically significant accumulation of porphyrins in urine, faeces, hepatic tissue and red blood cells on one hand, and an important decrease in the hepatic level of ATP on the other. These experiments agree with our earlier observations on the effects of 6-mercaptopurine[3] and orotic acid[4], which suggested that the experimental inhibition of ATP biosynthesis is accompanied by the appearance of porphyria. Granick[12] has recently observed that compounds capable of inducing an enhancement of porphyrin synthesis cause an increase in the activity of ALA-synthetase in liver mitochondria by stimulating a *de novo* formation of the enzyme. We did not note this phenomenon after the administration of ethionine, but it is possible that protein synthesis is inhibited by this toxin, as was suggested by Farber *et al.*[13]. On the other hand, Weber *et al.*[14] reported that ethionine is able to reduce the increased synthesis of certain enzymes occurring in liver influenced by inducing agents.

There are at least two ways by which we could explain the lack of a beneficial effect of adenine derivatives (inosine, AMP, ATP) on the disturbances of porphyrin metabolism caused by ethionine. First, as had previously been established under different experimental conditions[1,15,16], the effect of purine derivatives on excess porphyrin synthesis is directed on the synthesis of ALA. For example, in an illuminated suspension of *Rhodopseudomonas spheroides* in Lascelles mixture I (containing glycine and succinate as substrates), ATP at a concentration of 3 mM causes almost total inhibition of porphyrin synthesis. On the other hand, ATP is without effect when the micro-organisms are suspended in Lascelles mixture II (containing ALA as substrate[15]). It was reported by Gibson *et al.*[8] that ethionine stimulates porphyrin biosynthesis by *Rhodopseudomonas spheroides* in mixtures I and II to an equal extent. Thus, in ethionine intoxication part of the raised level of porphyrin synthesis may escape the inhibitory effect of adenine nucleosides and nucleotides. The second mechanism, which has arisen from our findings, is that the inhibition of excess porphyrin formation by these adenine derivatives results from the stimulation of the biosynthesis of a physiological inhibitor—which seems to be a protein and probably an enzyme[17]. The inhibitory effect of ethionine on protein synthesis and on the neoformation of adaptative enzymes in the hepatic tissue might thus explain, at least partly, the inefficacy of the adenine derivatives in alleviating the disturbances of porphyrin metabolism in rats with ethionine poisoning. This hypothesis is consistent with the observations of Farber *et al.*[13], who have recently emphasized that ATP administration prevents or reverses only some of the effects of ethionine intoxication. Furthermore, as they have shown, acute hepatic ATP deficiency leads to a complex biochemical disturbance involving several other metabolic pathways as well as those leading to an accumulation of porphyrins. Our present and earlier findings confirm this hypothesis.

Table 1

Mean values of etherosoluble porphyrins (copro + proto)

	Liver (μg/100 g liver wet weight) Ethionine intoxication	Liver (μg/100 g liver wet weight) Controls	Red blood cells (μg/100 ml.) Ethionine intoxication	Red blood cells (μg/100 ml.) Controls
(1) After 3 weeks of low protein diet (8 per cent casein) containing 0·5 per cent ethionine (4 intoxicated rats, 4 controls)	29·0	27·6 Difference not significant	116·5 ± 9·7 $t = 4·9$ $P < 0·01$	41·0 ± 8·8
(2) After 1 week of low protein diet (12 per cent casein), 50 mg ethionine daily by gastric tube (12 intoxicated rats, 12 controls)	17·1 ± 2·3 $t = 2·3$ $P < 0·05$	11·0 ± 1·0	62·0 ± 7·2 $t = 3·6$ $P < 0·01$	33·0 ± 3·5
(3) After 48 h of balanced diet, 100 mg ethionine daily by gastric tube (12 intoxicated rats, 6 controls)	13·6 ± 1·6 $t = 2·2$ $P < 0·05$	8·4 ± 1·4	—	—

Use of Carbon-14-labelled Arginine to measure the Catabolic Rate of Serum and Liver Proteins and the Extent of Amino-acid Recycling

THERE is evidence that in both man[1] and rat[2,3] protein deficiency causes a decrease in the catabolic rate of plasma albumin, which may plausibly be regarded as an adaptive reaction. To demonstrate this, it is necessary either to use a label which is not re-utilized, such as radio-iodine, or to reduce re-utilization to a minimum by injecting proteins that have been biosynthetically labelled in a donor animal. Tissue proteins cannot be studied by these methods, and therefore it is not known whether they react in the same way as plasma albumin to changes in dietary protein intake.

It has been shown by several workers that when labelled amino-acids are given, the rate of decay of radioactivity of both liver and plasma proteins is reduced in animals on a low protein diet[4,5]. This has been taken as evidence of a reduced catabolic rate of liver proteins, paralleling that of plasma proteins, but it could also result from recycling or re-utilization of the labelled amino-acid. To the extent that recycling occurs, the apparent half-life of any protein, calculated from the decay curve after

the administration of a labelled amino-acid, must be longer than the true half-life. The term "apparent half-life" is, of course, an approximation, because the decay curve is not strictly exponential.

In the experiments described here an attempt was made to separate these two phenomena—recycling and catabolism—and to measure simultaneously the true and apparent half-life of liver and serum proteins in normal and protein-deficient rats. Advantage was taken of the observation made by Swick[6] that the guanidine carbon of arginine, which is exchanged in the urea cycle, cannot be re-utilized. Assuming that virtually all the free arginine that enters the amino-acid pool goes through the urea cycle before it is incorporated in protein[7], when uniformly labelled arginine is incorporated into protein, the rate of decay of radioactivity in the 6-carbon (6-C) atom of arginine will be a measure of the true half-life of the protein, and the rate of decay in any or all of the other carbon atoms will give the apparent half-life.

Rats were given intraperitoneally 10 μc. of U-^{14}C-L-arginine, followed 18 h later by 100 μc. of carbon-14-labelled sodium carbonate in order to label the 6-C atom of arginine[8]. Two hours after this second injection a sample of liver (200–300 mg) was removed under ether anaesthesia. Blood samples (about 500 μl.) were taken from the tail daily for 3 or 4 days. At the end of this time the rat was killed and a second liver specimen obtained. Serum and liver proteins were precipitated with picric acid, and hydrolysed with 6 N hydrochloric acid. The specific activity of the 1-C atom of arginine was measured by treating one part of the hydrolysate with arginine decarboxylase in a micro-Conway unit. The carbon dioxide liberated was trapped in alkali in a planchet placed in the centre well, and counted after drying. The amount of arginine was measured with the same enzyme in the Cartesian diver microrespirometer[9]. The specific activity of the 6-C atom was measured by treating another portion of the hydrolysate with arginase. The urea produced was estimated by the method of Ceriotti and Spandrio[10]; carbon dioxide was liberated by reacting with urease, and collected and counted as before.

The true and apparent half-lives of mixed serum proteins were calculated from the slopes of the semilogarithmic plots of specific activity against time. The lines were fitted by the method of least squares. No correction was made for blood removed by sampling. The first sample used in the calculation was that obtained 24 h after the liver biopsy. Before that, equilibration between extra- and intra-vascular protein pools would probably not be complete. For calculation of the half-life of mixed liver proteins only two points were available, separated by an interval of 3 or 4 days.

Two experiments were carried out. In the first, two adult rats were given a protein-free diet for 3 days before the injection of labelled arginine, and kept on this diet for a further 4 days until the end of the experiment. In the second experiment three young rats (each weighing about 100 g) were given the protein-free diet for 10 days before the injection, and then for 5 more days until they were killed. In both experiments an equal number of rats of comparable weight were kept on a stock diet. With one exception the rats seemed to show no ill effect from the biopsy. In one rat (No. 26, Expt. 2) there was excessive trauma at the biopsy, and the rat lost weight afterwards, although it was on a normal diet. The results are shown in Table 1. In the five normal rats the average value for the true half-life of mixed serum proteins was 2·0 days. To study the mixed proteins is admittedly a crude approach, but with the amounts of serum available it was not possible to do the analyses on the separate protein fractions. In rats fed a high-protein diet, Jeffay and Winzler[2] found values of about 2·5, 0·7 and 5 days for the half-life of albumin, α-globulin and γ-globulin. Our figure for mixed proteins must represent a weighted average, and seems quite consistent with these findings. In the protein-deficient rats it seems that the longer period of depletion (experiment 2) did cause a reduction in the catabolic rate of the mixed proteins. The mean value for the true half-life in this group was 3·36 days. In the experiments of Jeffay and Winzler[2], a protein-free diet caused an increase in the half-life of albumin to about 4·5 days, but no increase in that of the globulins. Therefore, the increase in the half-life of the mixed serum proteins found in the present experiments must underestimate the real change in the catabolic rate of albumin. Excluding No. 26, which lost weight, in the normal rats the average for the apparent half-life is 2·7 days. In the protein-deficient rats it was doubled (mean 5·5 days).

Table 1

	Rat No.	Diet*	Weight† change (per cent)	Serum protein half-life (days) True	Serum protein half-life (days) Apparent	Liver protein half-life (days) True	Liver protein half-life (days) Apparent	Isotope‡ replacement ratio Serum	Isotope‡ replacement ratio Liver

* *N*, Stock diet. *PF*, protein-free diet, 3 or 10 days.
† Percentage of weight change during the experimental period.
‡ For definition see text.

The true half-life of liver protein in the normal rats averaged 1·9 days, and in the protein-depleted rats 2·3 days. This difference is statistically significant ($0·05 > P > 0·01$). It seems, therefore, that in protein deficiency there is a fall in the catabolic rate of mixed liver proteins, although the reduction is smaller than that found for plasma albumin by other workers[2,3]. The values for the apparent half-life are rather irregular, perhaps because of the disturbing effect of the liver biopsy. In all cases it is longer than the true half-life, and in some much longer.

The question arises as to whether from these results it is possible to define quantitatively the extent of "re-utilization". By this term is meant the incorporation into protein of amino-acids derived from the catabolism of body protein and not from food. Thus on a protein-free diet all synthesis must represent re-utilization. The specific activity of liver and serum proteins nevertheless falls because some of the amino-acid incorporated is derived from tissues such as muscle, which are poorly labelled. It seems probable that most of the isotopic amino-acid that is re-incorporated must have come from tissues which are highly labelled and are turning over rapidly. If so, the extent of re-utilization of isotope will be a measure of what might be called "internal" recycling within a pool of highly labelled protein. This pool roughly corresponds to the protein of the viscera and plasma; it contains about 20 per cent of the total protein of the body, but accounts for about 50 per cent of total protein turnover[11]. An index of the extent of this recycling of isotope can be calculated from the present results. If $F1$ is the true fractional rate of turnover of serum or liver protein, and $F2$ the apparent fractional rate, and if a steady state is assumed, the ratio $\frac{F1-F2}{F1}$ represents the proportion of isotope lost by catabolism that is replaced in the same time interval. The calculated values of this isotope replacement ratio are shown in the last column of Table 1. For serum proteins the ratio seems to increase with protein depletion, particularly in the early stage, before there is a reduction in catabolic rate. In liver the striking point is the high rate of replacement even in the animals on a normal diet, particularly in

view of the fact that arginine is only a semi-essential amino-acid. The results of Penn, Mandeles and Anker[12] suggest that the rate of re-utilization must be different for each individual amino-acid.

On the basis of kinetic data, Swick[6] was able to give a more precise definition of the extent of amino-acid re-utilization in the liver. He defines it as the probability that the carboxyl-carbon atom of arginine, liberated from liver protein by catabolism, will be re-incorporated in liver protein. Under his experimental conditions this probability was about 50 per cent. If in the present experiments all the arginine entering the liver pool from different sources had had the same specific activity, the "isotope replacement ratio" would be identical with the probability ratio calculated by Swick. The fact that they are of the same order of magnitude suggests that the isotope replacement ratio may be a useful indication of the extent of amino-acid re-utilization in the strict sense defined by Swick. Because an increase in the extent of re-utilization may be an important feature of the process of adaptation to low protein intakes, even an approximate quantitative measurement of the effect may be of value.

Intracellular Repressor of Alkaline Phosphatase

THE repression of β-galactosidase in *Escherichia coli* has been demonstrated to be sensitive to 2,4-dinitrophenol[1]. This presumably indicates that high energy phosphate bonds are involved. Alkaline phosphatase is repressed by *ortho*-phosphate in the medium. We have used this as a test to determine whether high energy phosphate bonds are essential to the mechanism of enzyme repression. Is the intracellular repressing phosphate *ortho*-phosphate or must it participate in a high energy compound for the formation of "active repressor"?

Cells of *E. coli B* were grown and alkaline phosphatase assayed as previously reported[2]. Addition of 0·001 M 2,4-dinitrophenol had no effect on enzyme production or repression. 0·01 M abolished enzyme synthesis. We were unable to find any concentration that stimulated alkaline phosphatase production. A similar result was obtained with arsenate. If, then, *ortho*-phosphate is itself the intracellular repressor, a phosphate acceptor which would reduce the intracellular concentration of *ortho*-phosphate should stimulate enzyme synthesis. Various nucleosides were tested, and it was found that inosine stimulated normal enzyme production and also reduced the amount of time required for recovery from repression by added phosphate (Fig. 1). A similar but less pronounced effect occurred with guanosine and adenosine.

Manson *et al.*[3] have discovered a mechanism for repression of alkaline phosphatase synthesis by *ortho*-phosphate in a particulate fraction of *E. coli*. Our observations make it more probable that the intracellular repressor is indeed *ortho*-phosphate and that their mechanism is the one operative *in vivo*. In view of this, the function

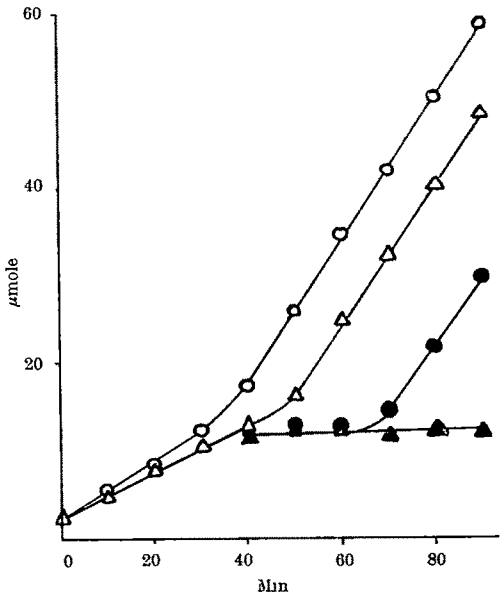

Fig. 1. *E. coli* was grown and the enzyme induced as previously described in run 1 (△). In run 2 (○) the induction medium was fortified with 0·01 M inosine. After 30 min, 0·001 M sodium monohydrogen phosphate was added to portions of run 1 (▲) and run 2 (●). 0·5 ml. portions were withdrawn at the times indicated and the enzyme assayed. The vertical scale represents micromoles of *p*-nitrophenyl phosphate hydrolysed in 60 min.

of the organic repressor the properties of which have been inferred[4] becomes even more obscure.

A Sex-determined Renal Calcification in Rats

AN examination of several hundred white Wistar rats from the only source of laboratory animals available to this institution revealed a 100 per cent incidence of renal calcification in female animals and a complete absence of this condition in males of the species. This situation also applied to pure line white Wistar, black Wistar and black and white Wistar strains but was not observed in several species of mice from the same source and fed the identical diet.

These animals were bred and maintained on a commercially produced feed pellet with a calcium and phosphorus content of 2·0 per cent and 1·6 per cent of the dry weight respectively. The relatively high level of these two elements was found to result from the use of bonemeal in the pellets. The renal calcification, however, could not simply be related to the intake of these minerals as female rats bred and raised on synthetic diets[1] (calcium 0·31 per cent, phosphorus 0·27 per cent) also showed invariable occurrence of the nephrocalcinosis. A satisfactory control diet was provided by the use of 'Farex' (Glaxo Laboratories, Ltd.), a supplemented, mixed cereal baby food, and milk (1 : 5 w/v). This diet had a content of 0·88 per cent calcium and 0·68 per cent phosphorus on a dry weight basis, and female rats were free of kidney deposits after even 6 months on this diet. The condition also did not occur in female animals raised on a low phosphorus rachitogenic diet[2] (calcium 1·42 per cent, phosphorus 0·28 per cent), which is not surprising in view

of its effect on mineralization and growth. With the exception of the rachitogenic diet, growth rates were high and comparable on these diets, with no difference observed between male and female rats.

Renal deposits of calcium were histologically demonstrable within 3 weeks of weaning female rats on to the standard pellets. The calcification commenced at the cortico-medullary junction, where it remained most dense throughout life, but later spread into the medulla. The cortex remained unaffected although there was some enlargement of the deposits with increasing age. Electron microscopy revealed the deposits to be usually lamellated and to be both intracellular and intra-tubular in location. A few deposits had the typical appearance of hydroxyapatite.

Table 1. RENAL CALCIFICATION IN WHITE WISTAR RATS

Sex	Age (weeks)	Diet	Treatment	Calcium	Phosphorus	Histology
M	26	*P*	—	0·38 ± 0·03	12·20 ± 0·46	Negative
F	6–8	*P*	—	1·12 ± 0·56	13·60 ± 0·80	Positive
F	26	*P*	—	12·10 ± 14·00	16·20 ± 6·0	Positive
F	11–18	*C*	—	0·37 ± 0·01	12·60 ± 0·35	Negative
M	5–11	*P*	Castrated	0·39 ± 0·05	13·10 ± 1·1	Negative
M	9–12	*P*	DHT	3·41 ± 2·80	14·20 ± 0·98	Positive
F	5–11	*P*	Ovariectomized	0·39 ± 0·05	13·60 ± 0·80	Negative
M and F	10	*P*	Gonadectomized + oestroform	3·96 ± 2·33	13·80 ± 0·32	Positive

P, Commercial pellet diet; *C*, control 'Farex' diet; DHT, dihydrotachysterol, 1 mg per 100 g body-weight by intraperitoneal injection; analytical data as means with standard deviations in mg/g dry weight of kidney, minimum of seven animals in each group.

Kidney mineralization following administration of hypercalcaemic agents such as parathyroid hormone, dihydrotachysterol and vitamin D is well known. With nephrocalcinosis induced by these agents there is a diffuse distribution of mineral throughout the kidney, the cortex being most affected[3]; death from renal failure is a common event with these treatments. A feature of the female-specific renal calcification described in this report is that the affected animals were apparently healthy, with normal weight gain, ability to withstand multiple pregnancies, normal serum calcium and phosphorus levels and no impairment of renal function as judged by blood urea measurements.

Experimental work has shown that the sex specificity of this nutritional nephrocalcinosis is related to oestrogen level. A group of female rats was ovariectomized and weaned at 30 g weight on to the standard pellet diet. Periodic examination of kidneys from these animals showed the absence of renal deposits over the 8 weeks of observation. In a similar experiment both male and female rats were gonadectomized and received 100 μg of oestradiol benzoate ('Oestroform', British Drug Houses, Ltd.) twice weekly by intramuscular injection while fed on standard pellets. Within 3 weeks all animals had developed the typical renal deposits. The results of some of these treatments are summarized in Table 1, which also gives analyses for total calcium and phosphorus in the decapsulated kidneys. These quantitative data give an index of the magnitude of the calcification and illustrate its progression with age in the female rats.

Both oestrogens and a dietary factor are implicated in the aetiology of the condition described. The nutritional factor remains undetermined, but it would seem that it is not related to absolute levels of calcium and phosphorus, vitamin D or magnesium in the diet.

Isolation of Fluorescent Components from Ox-bone Human Dentine and Gelatine

EARLIER investigations[1–4] on the fluorescent material in calcified tissues have indicated that it is associated with the collagenous organic matrix of these tissues. Observations on soluble tissue matrix preparations showed they had excitation maxima at 330 mμ with corresponding emission maxima about 400 mμ.

Using a 'Sephadex' ion-exchange column (C.25 *CM* at *p*H 4·2) we have now successfully separated the fluorescent material from alkaline hydrolysates of ox bone, human dentine and gelatine preparations with 80–90 per cent recovery. The isolated material possessed a characteristic ultra-violet absorption spectrum with maxima at 264 mμ and 325 mμ. The fluorescent excitation and emission maxima of the isolated material were 330 mμ and 400 mμ, respectively, and were identical to those obtained from both solid and solution preparations of the corresponding intact matrices. Fluorescence was destroyed by bromination and permanganate oxidation. The isolated material fractionated on a 'Sephadex *G*-10' gel filtration column into two components, with identical fluorescence characteristics.

Consideration has been given to the concepts that the fluorescence associated with calcified tissue proteins may arise either from a separate substance bound to the matrix or, alternatively, be the property of some intrinsic structural feature of the collagen molecule itself. Our results indicate that the fluorescent material survives alkaline hydrolysis of the total matrix, and can apparently exist as a separate entity, with the same excitation and emission characteristics in the isolated state as when associated with the matrix. It presumably possesses oxidation and bromination sensitive centres. From the gel-filtration results a tentative estimate of a molecular weight of less than 700 for the material may be made, the results also indicating that the fluorescence is associated with two fractions of differing molecular weight.

Freezing of Bound Water and Protein Aggregation in Frozen Cod Muscle stored near its Melting Point

THE muscle proteins of frozen fish slowly aggregate at a rate depending on the temperature. Since the reaction causes the flesh to become tough to eat, and eventually unacceptable to the consumer, a considerable research effort has been directed towards means of slowing it down—the usual method being to keep the temperature as low as possible.

In cod (*Gadus morhua* L.) air-blast frozen at −30° C the change proceeds most rapidly between −1° and −2° C (ref. 1), and it was therefore surprising to learn recently that fish landed in Portugal after storage on a catching vessel at temperatures just below their freezing point ("superchilled") had suffered little damage to their proteins[2]. The trials were repeated under laboratory conditions in this country[3] and, after thawing, the samples

were shown both by subjective examination and by the "Cell Fragility" technique[4] (a physical method for measuring cold-storage changes in fish muscle) to be almost unaltered, although the conditions were apparently such as to cause maximum change.

It seemed likely at first that the fish had never actually frozen: the proteins of cod muscle at −1·5° C in the supercooled condition (without ice present) do not aggregate[1]. However, calorimetry showed[3] that about half the tissue water was in fact frozen out after 8 days at an ambient temperature of −3° C.

The only difference between the fish showing the maximum rate of change just below their melting-point and the "superchilled" samples appeared to be the temperature at which each was initially frozen. The present report describes the results of keeping frozen cod at −1·6° C after freezing at different temperatures.

The anterior halves of fillets from cod about 60 cm long, caught by trawling near Aberdeen in August 1965, were chopped into seven or eight pieces. "Mixed samples" were made by placing fifteen such pieces, each weighing about 50 g, and each from a different fish, into a polythene bag and sealing under vacuum. Half of these "mixed samples" were frozen by placing in an air-blast freezer at −30° C, and the other half by placing in a large insulated bath of sodium chloride solution, continuously stirred and maintained at −3° C by adding solid carbon dioxide from time to time. The samples were removed from the blast-freezer after 3 h, and from the brine bath after ascertaining that ice was present in all the samples. Further time would elapse before the ice had completely permeated the brine-cooled samples; the present procedure was merely intended to guard against supercooling. The samples at −30° C were left in a room at −7° C for some hours before mixing with those frozen at −3° C. All were then placed in a small cabinet with internal temperature maintained at −1·6° C as already described[1], and a mixed sample of each kind was removed every 2 or 3 days for testing by the cell fragility method[4] after thawing at about 18° C.

The results are shown in Fig. 1, and it is clear that the samples frozen at −3° C deteriorated much more slowly than those air-blast frozen at −30° C, though both were stored at the same temperature.

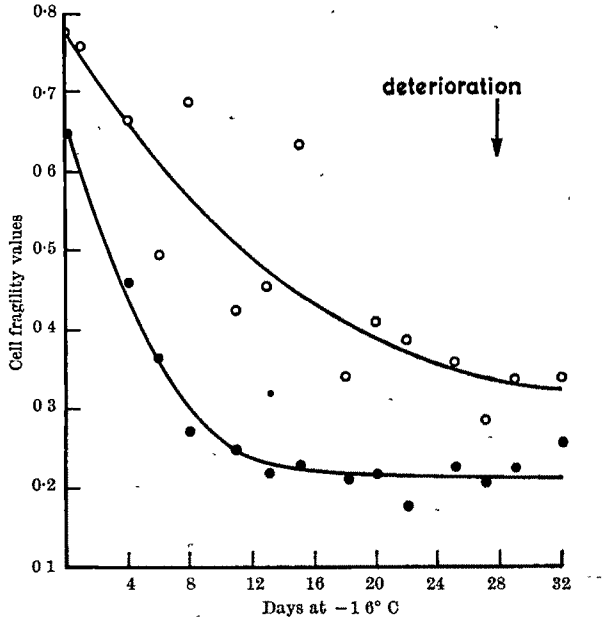

Fig. 1. Deterioration of the protein of frozen cod muscle stored at −1·6° C, as measured by the cell fragility method. Each point is the mean of fifteen determinations. ●, Fish frozen at −30° C and then warmed up to −1·6°. ○, Freezing initiated in a bath at −3° C.

Fish muscle appears to bind water with a variety of bond energies[5]. Progressively lowering the temperature causes the detachment of more and more bound water and its crystallization as ice, with a resultant increasing damage to the protein[6]. Rewarming the tissue does not reverse the situation—much of the extra ice remains at higher sub-zero temperatures[6], so that more is present in tissue warmed up to −1·6° C than in that cooled down to it. Because a greater proportion of the water is frozen, the tissue salts are more concentrated in the blast-frozen samples, and it has long been thought that concentrated tissue salts are, at least partly, responsible for the changes that occur in the proteins of frozen fish[7,8]. Herein probably lies the explanation for the effect shown in Fig. 1.

In his review of the freezing of tissue, Meryman[9] suggested that ". . . considerably more water remains frozen during warming than would have frozen at the same temperature during cooling". The effect was demonstrated experimentally by Love and Elerian[6], who found differences between the specific volumes of tissue cooled to, and warmed up to, −14° C. The findings of the present report seem to be another manifestation of the same phenomenon.

Discussing the new "superchilling" process, Partmann[10] concluded that the tissue would rapidly deteriorate unless it could be prevented from freezing. In the light of the present information, one can be more optimistic, especially where a relatively short storage time is contemplated.

The experimental work was carried out by Mr. John Smith. The work was carried out as part of the programme of the Ministry of Technology.

Studies on the Proteins from Chromaffin Granules of Ox, Horse and Pig

CHROMAFFIN granules of the adrenal medulla are cell organelles which contain catecholamines in a high concentration. It has been suggested that the proteins of these granules are involved in the storage of these catecholamines. So far only the proteins from the granules of ox adrenal medulla have been characterized. These proteins are highly soluble in water, and the purification as well as some properties of the main component of the soluble fraction have been reported[1–3]. Recently, it was shown that the secretion of catecholamines from the perfused ox adrenal medulla is accompanied by a release of this specific component[4].

In the present investigation we compared the solubility of the proteins in chromaffin granules from ox, horse and pig and the behaviour of the soluble fraction in starch-gel and polyacrylamide disc electrophoresis. This comparative investigation was thought to provide further evidence for the significance of these proteins for chromaffin granules.

Adrenal medullae of ox, horse and pig were homogenized in ice-cold 0·3 M sucrose. Nuclei and cell debris were removed by centrifugation at 12×10^3 *g*-min. The supernatant was centrifuged at $2{\cdot}4 \times 10^5$ *g*-min to

sediment the so-called "large granule" fraction which contains mitochondria, lysosomes and chromaffin granules[5]. 1·5 ml. of the resuspended sediment were layered on 5 ml. of 1·6 M sucrose and centrifuged at 8·4 × 10^6 *g*-min. By this method chromaffin granules were obtained as a sediment. 42–47 per cent of the total catecholamines present in the homogenate were recovered in this final sediment. For the determination of the solubility of the proteins the chromaffin granules and the mitochondrial fraction were lysed in 0·005 M citrate buffer (*p*H 6·3) and the insoluble material was spun down at 9 × 10^5 *g*-min. After addition of trichloroacetic acid (TCA, final concentration 5 per cent) to both sediment and supernatant the precipitates obtained were extracted with boiling alcohol–ether (3 : 1 v/μ) and their protein nitrogen was determined by the micro-Kjeldahl method.

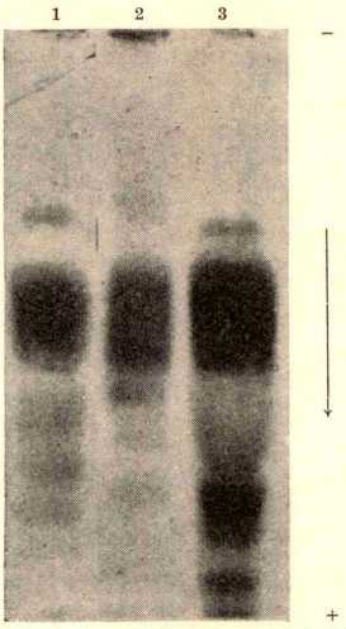

Fig. 1. Vertical starch-gel electrophoresis (ref. 6) of the soluble proteins of chromaffin granules from the adrenal medulla of (1) ox; (2) pig; (3) horse.

Under these conditions 70 ± 1 per cent of the proteins in ox granules, 74 ± 2 per cent in horse granules and 57 ± 1 per cent in pig granules were water-soluble. The corresponding values for the mitochondrial fraction were between 20 and 32 per cent. A resolution of the soluble proteins of chromaffin granules into several bands was obtained with vertical starch-gel electrophoresis[6]. The result of one experiment is shown in Fig. 1. It is evident that in all three species there is a main protein component which migrates to the same position. Several smaller components do not show any correspondence. Comparable results were obtained by polyacrylamide disc electrophoresis. Scanning (by 'Chromoscan') of the starch-gel patterns showed that the main component represents 49 ± 6 per cent of the total soluble proteins from ox granules, 59·5 ± 6 per cent from horse granules and 73·5 ± 5 per cent from pig granules.

We conclude that a high solubility and the presence of a main component which migrates to the same position in starch-gel electrophoresis are characteristics of the proteins of chromaffin granules of all three species examined. If these soluble proteins are essential to the function of chromaffin granules, then the main protein component which was found to be common to all species examined is most likely to be involved.

We are grateful to Prof. A. Schinzel for putting at our disposal his ultracentrifuge, and to Miss B. Merkle for technical assistance.

Effect of Glucose on the Denaturation of Glucose Dehydrogenase by Urea

GLUCOSE dehydrogenase from spores of *Bacillus cereus* is heat stable in solutions of sodium chloride at *p*H 6·5 (ref. 1). Increasing concentrations of sodium chloride also protect the enzyme from inactivation by 8 M urea. The enzyme has a half-life of 7 min in 8 M urea, *p*H 6·5, but in 8 M urea : 1 M solutions of sodium chloride, the half-life of the enzyme is 192 min. The rate of decay of glucose dehydrogenase activity in the presence of urea follows second order kinetics[2]. A number of enzymes can be protected from urea inactivation by their specific substrates[3–8]. In this communication we report the effect of glucose in stabilizing glucose dehydrogenase and partially reversing the inactivation resulting from urea.

The preparation, purification, specificity and assay of glucose dehydrogenase have been reported elsewhere[1,9]. All experiments were performed at 0° C in 0·05 M phosphate buffer, *p*H 6·5. Fresh urea solutions (Baker, C. P.) were prepared for each experiment in order to eliminate the possibility of cyanate formation and its subsequent interaction with the protein[10]. The enzyme was incubated with 8 M solutions of urea containing 0–1·0 M glucose, and at various times samples were taken and assayed for enzyme activity. The reciprocal fraction activity remaining was plotted against time as shown in Fig. 1.

Concentrations of glucose as low as 0·1 M increased the half-life of the enzyme from 7 min to 90 min and further protection was achieved as the concentration of glucose was increased from 0·1 to 1 M. The decay of the enzyme at all concentrations of glucose was a second order function. Furthermore, the enhancement of stability of the enzyme was half-power with respect to glucose. We interpreted these data to mean that glucose binds to two "urea sensitive" groups on the protein. The denaturation

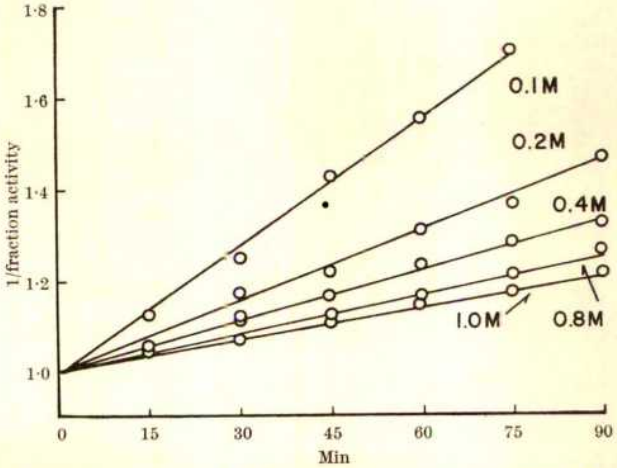

Fig. 1. Inactivation of glucose dehydrogenase by 8 M urea in the presence of various concentrations of glucose. The reaction was carried out in 0·05 M phosphate buffer, *p*H 6·5, at 0° C.

caused by 8 M urea could be partially reversed. Glucose dehydrogenase was treated with 8 M urea for 25 and 45 min and the loss of enzyme activity was determined. After this, the samples were dialysed against phosphate buffer, phosphate buffer + 2·5 M sodium chloride and phosphate buffer + 1 M glucose. In each instance 3 ml. of the enzyme mixture in 8 M urea was dialysed against 500 ml. of solution for 3 h at 4° C. The initial activity of the enzyme without urea was 8,000 U. The results are shown in Table 1.

Table 1. DENATURATION OF GLUCOSE DEHYDROGENASE BY 8 M UREA AND ITS PARTIAL RECOVERY FOLLOWING DIALYSIS

Time of incubation with 8 M urea	Activity of enzyme after incubation with 8 M urea (U)	Activity after dialysis against phosphate buffer (U)	Activity after dialysis against phosphate buffer + 2·5 M sodium chloride (U)	Activity after dialysis against phosphate buffer + 1 M glucose (U)
25 min	4,500	4,500	4,600	6,250
45 min	3,000	4,400	4,200	6,200

In both treatments (25 min and 45 min) the degree to which renaturation of the enzyme occurred after dialysis against 1 M glucose was identical. After 45 min incubation with 8 M urea the enzyme activity was reduced to 37 per cent, but after dialysis against 1 M glucose, the level of enzyme activity increased to 77 per cent of the original activity. There was thus a partial recovery of 40 per cent. However, only 12 per cent of the enzyme was renatured when the urea inactivated enzyme was dialysed against phosphate buffer or phosphate buffer + 2·5 M sodium chloride.

The following experiment was designed to determine whether prolonged exposure of the enzyme to urea, which results in complete denaturation of the enzyme, would still enable partial recovery to take place when the denatured enzyme was dialysed against 1 M glucose (Table 2).

Table 2. EFFECT OF PROLONGED EXPOSURE TO UREA FOLLOWED BY DIALYSIS AGAINST 1 M GLUCOSE

Concentration of urea	Activity remaining after 90 min (per cent)	Activity after dialysis against 1 M glucose (per cent)
5 M	67	100
8 M	3	0

The enzyme was incubated with 5 M and 8 M urea for 90 min. The reaction mixtures were dialysed against 1 M glucose in 0·05 M phosphate buffer, *p*H 6·5 at 4° C for 20 h. The prolonged exposure to 8 M urea resulted in irreversible denaturation of the enzyme (Table 2). Thus, the extent of reversibility appeared to be a function of the exposure time and concentration of urea. Table 1 shows that some irreversible denaturation also occurred when the enzyme was treated with 8 M urea for 25 min. At a lower concentration of urea (5 M) there was complete reversibility even after a prolonged exposure of 90 min. The denatured enzyme (8 M urea for 30 min) was also dialysed against 1 M solutions of galactose, fructose, α-methylglucoside, mannose and sucrose, but these were no more effective than phosphate buffer in reversing the inactivation.

Rajagopalan, Fridovich and Handler[5] have investigated the inhibition of a variety of enzymes by urea. They found that urea inactivation was most pronounced in enzymes utilizing large organic molecules as substrates. The inhibition of urea inactivation by the substrate was invariably competitive for such enzymes but not for those utilizing inorganic substrates. Our investigations show that the inhibition of urea inactivation of glucose dehydrogenase by glucose was also competitive. The substrate effect was specific and other monosaccharides, differing only in the configuration of a single carbon atom, afforded no protection. This was also true for the inactivation of the enzyme by 5-dimethylaminonaphthalene sulphonyl chloride where only glucose or glucose-6-phosphate would protect the enzyme[1].

This investigation was supported by a research grant from the National Institute of Allergy and Infectious Disease.

PATHOLOGY

Antitumour Activity of *N*-Hydroxyurethane

N-HYDROXYURETHANE ($C_2H_5O—\overset{\overset{O}{\|}}{C}—NHOH$) is known to be a carcinogen and to induce certain chromosomal aberrations[1,2]. It contains the hydroxamic acid group, a moiety apparently essential for the antitumour activity of hydroxyurea ($NH_2—\overset{\overset{O}{\|}}{C}—NHOH$) and its congeners[3,4]. For this reason, it was considered of interest to determine whether *N*-hydroxyurethane was active against various transplantable mouse tumours.

Daily doses of *N*-hydroxyurethane were administered subcutaneously to mice bearing various tumours. Table 1 presents the optimal dose for each tumour. A variant of the transplantable acute lymphoid leukaemia *L*1210 resistant to *N*-hydroxyurethane (*L*1210/*N*-hydroxyurethane) was produced by treating *L*1210 mouse leukaemic cells for several generations with daily doses of 400 mg *N*-hydroxyurethane/kg.

N-Hydroxyurethane was active against leukaemia *L*1210 and a variant of *L*1210 resistant to cytosine arabinoside (*L*1210/cytosine arabinoside). *N*-Hydroxyurethane was less active against the mast cell tumour *P*815 and leukaemia *P*288 and showed little or no activity against the plasma cell tumour *YPC*-1. Hydroxyurea, which gives a 50–65 per cent increase in median survival against advanced leukaemia *L*1210 at daily optimal doses of

Table 1. ANTITUMOUR ACTIVITY OF *N*-HYDROXYURETHANE IN VARIOUS MOUSE TUMOURS

Tumour	Range of doses (mg/kg)	Daily optimal dose	Day treatment initiated	Median survival time Control	Median survival time Treated	Increase in survival over control (per cent)
Leukaemia *L*1210	50–1,000	400–500	6	9·0	12·0	34*
*L*1210/cytosine arabinoside	200–600	400–600	6	9·5	14·0	47
*L*1210/*N*-hydroxyurethane	100–500	400	6	9·0	9·0	0
*P*815 mast cell	100–500	500	1	10·0	12·5	25
		300–400	6	10·0	11·5	15
*P*288 leukaemia	100–600	400–600	5	9·5	11·5	21
YPC-1 plasma cell	100–600	400–500	6	13·0	13·5	4

* Range of 25–42 per cent in five experiments.

250–500 mg/kg, seemed to be cross-resistant to *L*1210/*N*-hydroxyurethane (increase in survival time of 17 per cent at daily optimal doses of 600–750 mg/kg). *N*-Hydroxyurethane was inactive in mice bearing this resistant variant. Thus, it appears that these two antitumour agents have the same mechanism of action. *N*-Hydroxyurethane is carcinogenic and active against leukaemia *L*1210 whereas hydroxyurea is not carcinogenic[5] but active against *L*1210. Urethane ($C_2H_5O—\overset{\overset{O}{\|}}{C}—NH_2$) is carcinogenic but ineffective against advanced leukaemia *L*1210. These data suggest that the ethyoxy group (present in both urethane and *N*-hydroxyurethane) may be involved in carcinogenesis whereas the hydroxamic acid group is responsible for antitumour activity.

PHYSIOLOGY

Standing Waves Inside the Heart

SINCE Wetterer and Pieper[1] introduced their miniature high-resolution electronic pressure transducers, it has been possible to measure accurately phasic pressure changes inside the ventricular and atrial cavities of the mammalian heart beating *in situ*.

We measured pressure changes in the right ventricle and the right atrium of the heart of dogs which had been anaesthetized with morphine sulphate (2·5 mg/kg body-weight), sodium diallylbarbituric acid (25 mg/kg body-weight), urethane (200 mg/kg body-weight) and sodium pentobarbital (10 mg/kg body-weight).

The electronic pressure transducer used in our study was constructed according to the technique devised by Wetterer and Pieper[1] and mounted on the tip of a plastic catheter; pressure changes were measured by means of three lateral holes in a stainless steel cap covering the pressure-sensitive membrane. This manometer, together with the amplifier and the recording instrument, had a resonant frequency far greater than 100 c/s.

The chest of a dog was opened under anaesthesia and, maintaining the animal in this condition, the miniature catheter tip manometer was placed inside the apical region of the right ventricle by way of the right jugular vein with the aid of a fluoroscope. The right ventricular pressure was continuously measured at 100 mm/sec recorder speed, while the manometer was drawn slowly back into the right atrium while under fluoroscopic observation. At the onset of diastolic relaxation a sudden fall in pressure occurred, which indicated a transient pressure oscillation, probably corresponding with diastolic suction of blood from the atrium into the ventricular cavity (Fig. 1). We found that the amplitude of this negative-pressure oscillation varied continuously along the apex to base axis, and that it was maximal at the apex and zero in the region of the atrio-ventricular valve (Fig. 1). Moreover, a damped pressure oscillation over 1·5 wavelength can be observed at the apex of the right ventricle.

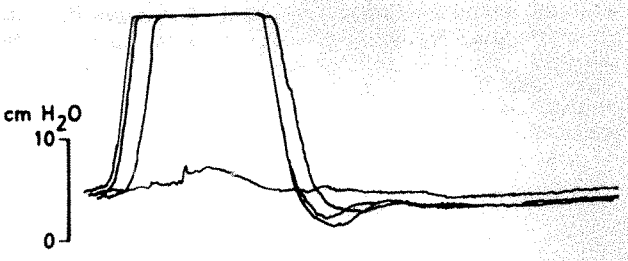

Fig. 1. Superimposed pressure curves recorded within the right heart of a dog, when a pressure transducer is continuously withdrawn from the ventricular apex into the atrium. The curves have been shifted slightly to the right in order to emphasize changes in amplitude of the early diastolic pressure dips.

These observations suggested that the heart chamber acts as a resonating cavity where standing waves occur, during diastole, between the apex and the fairly open central venous system. The wavelength associated with the ground frequency of these early diastolic oscillations would be four times the apex to base length, measured along the central axis of the heart (Fig. 2).

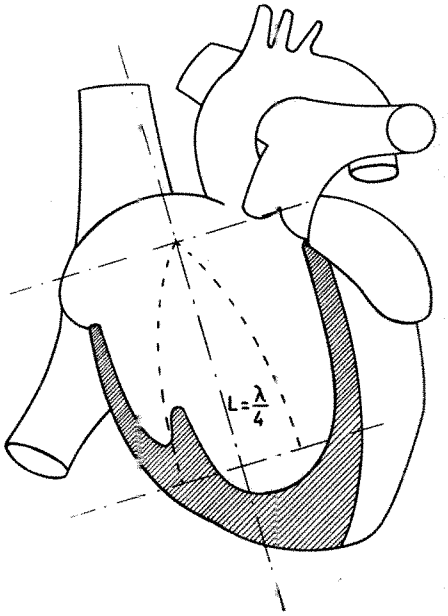

Fig. 2. Schematic representation of the right ventricle during diastolic time.

The relation between the apex to base length (L), the period of the oscillation (T) and the pressure wave velocity (v) is given by

$$\frac{4L}{T} = v$$

Such a relation provides a means for estimating the dimensions of the heart at diastole once the wave velocity is known.

If we consider the heart chamber to be an elastic cylindrical reservoir of known volume with a modulus of elasticity K, we can calculate the wave velocity from a variant of the Moens–Korteweg equation[2,3]

$$v = \left(\frac{K}{\rho}\right)^{\frac{1}{2}} \quad c = 0{\cdot}974 \ (K)^{\frac{1}{2}}$$

where $K = V\frac{dP}{dV}$, P, the pressure inside the ventricle (dynes cm^{-2}), V is the ventricular volume (cm^3), and ρ is the density of blood (1·055 g cm^{-3}).

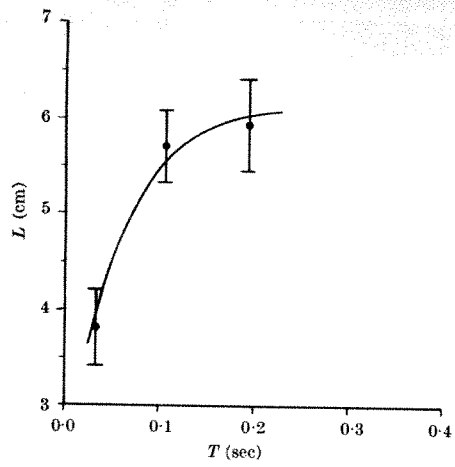

Fig. 3. Apex to base length of the right ventricle in function of early diastolic time. Averages are calculated over ten consecutive heart beats.

Because precise data for the volume elasticity of the right ventricle of dogs were not available, we calculated K from data given by Gauer[4] and Sandler[5] for man. This gives a value for the wave velocity of about 128 cm sec^{-1}. The average axial length L calculated from each of the three half-periods, which can be observed at the apex, is represented as a function of time in Fig. 3. The rapidly converging curve provides further evidence for the suggestion that diastolic filling is nearly complete at early diastole.

Dependence of Velocity of Structural Breakdown of Injured Cross-striated Muscle Fibres on Time of Denervation

THIS communication reports some results of investigations of the structural breakdown after denervation of muscle. The experiments indicate the extent to which intracellular factors play a part in the process of structural breakdown of injured muscle fibres.

Research into the process of structural breakdown in injured cells is of interest in the study of muscular pathology and for an explanation of elementary mechanisms of muscle contraction. Previous investigations dealt mainly with the influence of extracellular factors on structural breakdown. According to Rothschuh[1], and our earlier findings[2], the process of structural breakdown is based on at least two processes: (1) a contraction which may vary in its intensity; (2) a decay of organized structures. It is probable that proteolytic enzymes play some part in the second process.

It has been shown that the activity of myosin-ATPase decreases after denervation. According to Fischer[3], after denervation the activity of myosin-ATPase decreases only a little at first, but after a fortnight the decrease becomes more marked, probably because of weaker binding of ATP to myosin. At the same time, a change in the molecular shape of proteins seems to occur, as a result of which myosin and actin combine to form a stable complex[4]. The diminished ability to contract may be a result of the change in activity of ATPase and the molecular changes of the muscle proteins. Further investigations showed an increase in proteolytic activity[5,6].

The question remained of whether these changes were also reflected in the processes of structural breakdown. In our experiments we used male white rats weighing, on average, 200 g. Denervation of the right caudofemoralis muscle was accomplished by splitting the sciatic nerve near the vertebral column and excising a 1·5 cm piece of the nerve with all its branches. The corresponding muscle of the other leg served as a control. Preparation of the muscle fibres was carried out 10, 21 and 42 days after denervation. The distance from the nerve of the muscle fibres which decayed in unit time was used as a measure of the velocity of structural breakdown: measurements were made by means of microphotographs. Bundles of muscle fibres with four to five fibres were used, and these were obtained by carefully picking the muscle to pieces.

Fig. 1 shows the change in the velocity of structural breakdown as compared with that in the control muscle. Ten days after denervation there are no important changes in the velocity of structural breakdown. The velocity of breakdown in the denervated muscle amounts to $17{\cdot}44 \pm 1{\cdot}44\mu$/min. In the control the velocity is $15{\cdot}50 \pm 1{\cdot}43\mu$/min. The differences between the denervated muscle and the control are within the range of variation and are not significant ($P > 0{\cdot}25$, $t = 0{\cdot}95$).

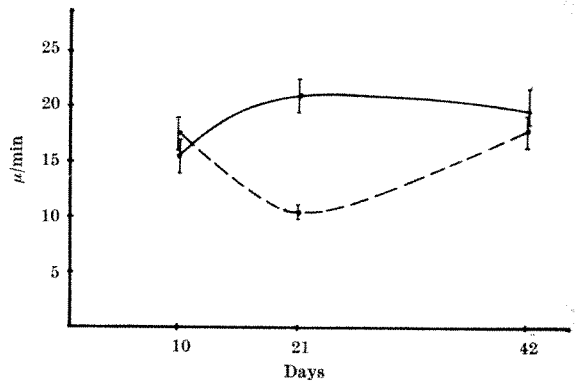

Fig. 1. Changes in velocity of structural breakdown dependent on denervation time compared with the control muscle. — — — — —, Denervated muscle; ———, control muscle.

By comparison with the control, a decrease in the velocity of structural breakdown becomes obvious after 21 days. The velocity of structural breakdown of the denervated muscle is $10{\cdot}55 \pm 0{\cdot}59\mu$/min whereas for the control it is $20{\cdot}87 \pm 1{\cdot}64\mu$/min. These results were obtained with many animals at different times. The difference between the velocity of structural breakdown of denervated muscle and control muscle can be considered significant ($P < 0{\cdot}001$, $t = 7{\cdot}15$). The different velocity of structural breakdown of control muscles after 10 and 21 days of denervation is not statistically significant. Further investigations are required of the possible velocity change in structural breakdown of control muscle. The measurement of velocity of structural breakdown 42 days after denervation is difficult owing to considerable atrophy of the muscle. This may injure the fibres and thus influence the measurements obtained. The result of this investigation does not show a significant difference ($P > 0{\cdot}25$, $t = 0{\cdot}83$) between the velocity of structural breakdown in the denervated muscle ($17{\cdot}82 \pm 0{\cdot}65\mu$/min) and the control ($19{\cdot}83 \pm 1{\cdot}76\mu$/min). The results of previous investigations on structural breakdown, and those of our own, considered in the context of the aforementioned hypothesis of the elementary processes of structural breakdown, lend support to the idea of successive contraction and structural breakdown.

Twenty-one days after denervation, the ability to contract is decreased. If it is accepted that contraction and proteolysis are separate and successive processes in structural breakdown, it is clear that, with a decreased ATPase activity and a diminished contractability, proteolysis will not be effective in breaking down the structure.

Fig. 1 shows an increase in the velocity of structural breakdown 42 days after denervation. Further investigations must be carried out to determine that this is not an experimental artefact and to find whether this increase is caused by secondary factors acting during this period or by primary factors.

In vitro Maintenance of Rabbit Sperm at Room Temperature

MAMMALIAN germ cells have been utilized by several investigators for the investigation of the biochemical and physiological mechanisms of senescence in living cells[1]. Functionally and metabolically active bovine sperm have been successfully maintained and studied at room temperature for a period of 6 days or more[2]. The results of these studies led to the present work in which two chemically defined media were used to maintain large numbers of vigorously motile rabbit sperm. The two media tested here were 'Coconut Milk Extender' (CME)[3] and Norman-Johnson solution No. 2 (N-J-2)[4], a chemically defined medium. Over a 6 day period of storage at room temperature (24° ± 2° C), N-J-2 proved to be the more satisfactory medium for supporting survival and activity of the sperm.

The acrosome of the mammalian sperm is a relatively unstable structure which may become detached from the sperm. Bedford[5] reported that, as a result of *in vivo* ageing in the female reproductive tract, there was an increase in the loss of the acrosome cap from rabbit sperm. In our investigation it was found that *in vitro* ageing alone at room temperature in the two media did not increase acrosome cap loss from rabbit sperm.

The procedures used in this work were as follows: ejaculated sperm were obtained with an artificial vagina from ten hybrid male rabbits; the semen was pooled and the sperm were washed free of seminal plasma by gentle centrifugation (700*g* for 15 min) within 30 min of collection. The washed sperm were divided into two parts; one part was diluted with N-J-2 and the other part with sodium citrate buffered medium containing 15 per cent coconut milk, to give a final concentration of 10–12 × 10^6 sperm per c.c. Plastic vials (2 c.c. capacity) were filled completely with the suspended cells and tightly capped to maintain a relatively anaerobic state during a 6 day period of storage. The vials were kept in the dark[3] at ambient room temperature (22°–26° C). Fresh vials of extended sperm were removed every day for 6 consecutive days, thoroughly mixed and then examined and rated according to the following: (1) sperm motility, which was qualitatively rated by means of an arbitrary scale described by Norman *et al.*[6]; (2) concentration of the motile cells and concentration of the stored sperm—these were determined with the use of a haemocytometer; (3) loss of acrosome cap. To determine the number of cells which had lost their caps, samples of sperm were prepared as smears, fixed in formal-saline and stained in buffered Giemsa stain[7].

Table 1 summarizes the results of five replicates in the two different dilution media. The number of live cells appeared to be greater in CME after 6 days of storage than in N-J-2; however, a greater number of cells were found to be motile in N-J-2. The quality of motility of the cells dropped drastically after the second day of storage in CME but not in N-J-2. This may be the result of the presence of chloride ion in N-J-2, which may serve as a metabolic inhibitor, enabling the cells to conserve some of their energy for a later activity. CME contains calcium nitrate and it is known that nitrate enhances rabbit sperm metabolism[8]. It seems evident that in CME most of the energy source was used up during the first few days after which motility and the number of live cells decreased quickly.

Table 1. EFFECT OF NORMAN–JOHNSON SOLUTION NO. 2 AND 'COCONUT MILK EXTENDER' ON MOTILITY, SURVIVAL AND LOSS OF ACROSOME CAP OF RABBIT SPERM KEPT AT ROOM TEMPERATURE FOR 6 DAYS

Diluent	Sperm age in days	Percentage of sperm alive	Percentage of sperm motile	Quality of motility*	Percentage of sperm which lost acrosome cap
CME	0	91	92	5·0	10
	3	82	77	2·1	11
	6	72	64	1·3	13
N-J-2	0	89	91	4·9	9
	3	83	83	3·1	10
	6	69	72	1·8	12

* 0 (non-motile), 1 (vibratory), 2 (poor progressive), 3 (fair progressive) 4 (good progressive), 5 (excellent progressive).

After 6 days of storage some of the cells from both media were centrifuged and resuspended in fresh CME containing calcium nitrate and 5 per cent egg yolk. It was found that the motility of cells stored in CME could not be restored to better than "fair progressive". However, the motility of sperm stored in N-J-2 and later resuspended was restored to better than "good progressive". It was also found that a much higher percentage of the cells stored in N-J-2 responded favourably to resuspension than cells stored in CME. It was concluded that the prolonged maintenance of an economically usable number of functionally active rabbit sperm, at room temperature in N-J-2, can be of advantage in artificial insemination. N-J-2 was found to be a better diluent for storing rabbit sperm at room temperature because a greater number of cells remained motile over the storage period; and because a considerably larger percentage of the cells could be reactivated by resuspension.

In vitro ageing increased acrosome cap loss by only 3 per cent in both diluents; but this increase was not found to be significant ($P > 0.05$). These observations seem to contradict those of Bedford. However, it is possible that the increase in acrosome cap loss that Bedford observed did not result from ageing alone, but possibly from the combined effects of ageing and the physiological environment of the female reproductive tract.

Vascular Migration of Transplanted Trophoblast in the Golden Hamster

THIS communication presents some preliminary results of an investigation of the invasive properties of hamster trophoblast transplanted to extra-uterine sites. The hamster is of particular interest in this respect, for in the course of normal gestation the trophoblastic giant cells exhibit a remarkable migratory activity not described in any other species[1]. The tertiary trophoblastic giant cells are extremely migratory and deeply invade the maternal arterial system. They are found in the mesometrial arteries for as long as 3 weeks *post partum*.

Donor hamsters were killed 6·5 days *post coitum* and the ectoplacental trophoblast dissected from the embryonic pole of the conceptuses. The hamster differs from the mouse and rat in that the ectoplacental tissue is not in the form of a cone but sits like a cap on top of the embryonic sac. A few hamsters were killed 3·5 days *post coitum* and the blastocysts flushed from the uterine horns with saline. The testis was initially chosen as the site for transplantation because it has been shown in the mouse to provide a very favourable environment for the development of eggs and ectoplacental cones[2,3].

Two days after transplantation beneath the tunica albuginea of the testis the ectoplacental cap proliferates into a nodule of trophoblast tissue at the site of inoculation. This proliferation opens up the blood system in the testis and produces haemorrhagic channels between the seminiferous tubules at the periphery of the graft. The first migratory movements of the trophoblast cells occur down these channels, in the interstitial cell areas. From 2–4 days after transplantation trophoblast cells can be seen in various stages of migration away from the original site of inoculation. They take up residence within the vascular system of the testis and line the wall of the vessels with their cytoplasm flattened in close contact with the endothelial surface. The way in which penetration of the blood vessels occurs is not yet apparent. It is possible that there is only one site of breakdown and all the trophoblast cells migrate in at this point. Trophoblast is potentially capable of invading tissues both by phagocytosis[4] and cytolysis[2,3], and it seems likely that one or both of these mechanisms is effecting this penetration.

During the early stages following transplantation there is some degeneration of surrounding seminiferous tubules, but not to the extent reported during trophoblast invasion of the testis in the mouse[3]. The presence of the developing hamster trophoblast induces numerous multinucleate spermatids in the tubules surrounding the graft, a phenomenon also seen in the mouse[2] and the guinea-pig[5]. Six days after transplantation almost all the trophoblast cells have left the original site of inoculation, which is marked only by a small patch of degenerate seminiferous tubules. The trophoblast cells are seen forming an almost continuous lining to the vessels nearby (Fig. 1), and a few are present in vessels further away. By the twelfth day (the longest period yet studied) the cells have become distributed throughout much of the vascular system of the testis. They still retain their characteristic morphology and staining properties. Whether they can survive longer, and migrate outside the testis itself, has yet to be discovered.

The migratory activity of the trophoblast is not limited to cells derived from the ectoplacental cap because transplantation of the hamster blastocyst to the testis produces trophoblast cells which follow a similar invasive pattern. This appears to be the first report of successful extra-uterine development of the hamster egg.

To test whether this ectopic migratory behaviour of hamster trophoblast is limited to the environment of the hamster testis, ectoplacental caps from the hamster were transplanted to the testes of adult hybrid mice. Autopsy after 6 days revealed hamster trophoblast cells in the vascular system of the mouse testis. The reciprocal experiment of transplanting mouse trophoblast to the hamster testis showed the development of a nodule of normal trophoblast tissue, but no migratory activity. It would seem that migration is an independent property of hamster trophoblast and is largely uninfluenced by the environment. It is also of interest that in these trans-specific transplantations there is no apparent immunological reaction against the trophoblast at the stages examined.

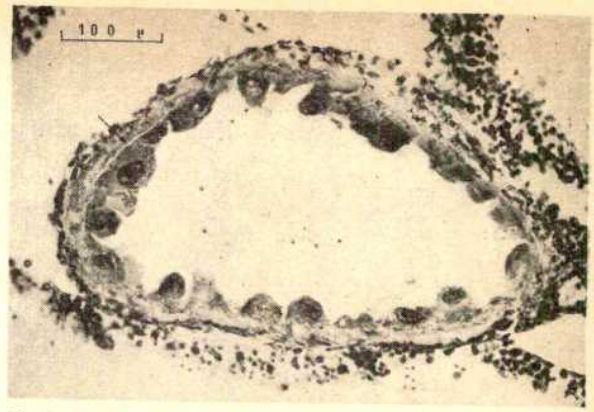

Fig. 1. Trophoblast cells lining the endothelial wall of an artery in the hamster testis. The endothelium is intact, but shown in clear focus only in the section arrowed. Seminiferous tubules and interstitial cells surround the artery.

The only other extra-uterine site to which hamster trophoblast has yet been transplanted is the kidney. The ectoplacental cap, placed beneath the kidney capsule, proliferates to produce a nodule of trophoblast tissue which also undergoes some migratory movement. Eight days after transplantation a number of trophoblast cells can be seen attached to the endothelial wall of blood vessels in the boundary zone of the kidney. However, a large number of cells still remain under the kidney capsule after this period. It may be that the more compact nature of kidney tissue limits the migratory movements of the trophoblast.

In the testes examined so far, the trophoblast cells appear to have migrated into the arterial network. This is based on observation of the characteristic histological appearance of arteries. However, in some instances, particularly the small capillaries, it is more difficult to identify the arterial nature of the vessels. If the migration is solely arterial this phenomenon is directly comparable with the situation in normal hamster pregnancy, where the tertiary trophoblastic giant cells show selective invasion of the arteries and are never found in veins. Orsini has found that these giant cells bring about pronounced changes in the arteries, which become dilated and thin-walled and lose their characteristic structural appearance[1]. These changes are probably brought about by some secretion of the giant cells. An exhaustive examination of serial sections of the testes is necessary before it is possible to say whether such an effect is produced in the testicular arteries.

The hamster trophoblast cells must possess some tropism, possibly towards oxygen tension, in order to invade preferentially the arterial system. Once inside the artery they have to migrate against the flow of blood, and this seems to be achieved by movement along the endothelial wall. The function of the trophoblast cells in this situation is entirely obscure. Their function during early gestation is primarily an invasive one to establish intimate connexion between mother and embryo, and it is difficult to understand the advantage of continuing an invasion into the maternal blood system. The only other known occasion when trophoblast tissue is found normally in the maternal blood system is in man. During the latter half of normal pregnancy, fragments of syncytial trophoblast break away from the placenta and are deported to the uterine veins[6]. Their function is unknown, but

it has been suggested that they may be of immunological importance[6]. They are probably normally broken down by some lytic mechanism in the circulating blood, although large numbers may reach the lungs. The phenomenon of trophoblast deportation to the lungs during normal pregnancy has also been reported for the chinchilla[7] (also personal observation).

These results show that extra-uterine transplantation, particularly to the testis, may be a profitable technique to investigate further the remarkable migratory behaviour of hamster trophoblast cells.

Effect of Degraded Carrageenin on Gastric Secretion Stimulated by Histamine and 'Histalog'

THERE is some evidence that in the guinea-pig, the oral administration of degraded carrageenin, a sulphated polysaccharide, causes a slight temporary reduction of gastric acidity in response to histamine[1]. We have had occasion to study the effect on gastric secretion when degraded carrageenin is administered subcutaneously. The results indicate that carrageenin parenterally has a pronounced inhibitory action on the acid secretory response to histamine but, somewhat paradoxically, not on the secretory response to 'Histalog' (betazole hydrochloride), a structural isomer of histamine.

Gastric juices were obtained from fasted unanaesthetized adult male guinea-pigs by intubation 1 h after the intramuscular injection of an aqueous solution of histamine acid phosphate (1 mg/kg) or 'Histalog' (100 mg/kg). Degraded carrageenin (5 per cent aqueous solution) had been injected subcutaneously 9 h previously in a dose of 400 mg/kg body weight. The results are shown in Table 1.

Table 1. EFFECT ON STIMULATED GASTRIC SECRETION OF DEGRADED CARRAGEENIN ADMINISTERED SUBCUTANEOUSLY

(Means ±1 *S.D.*)

Treatment and No. of animals	Gastric secretion: Volume (ml.)		Gastric secretion: Total acid conc. (m.equiv/l.)	
Histamine only (10)	8·9 ± 2·2	$P < 0.01$	128·6 ± 8·2	$P < 0.001$
Carrageenin + histamine (10)	3·7 ± 3·3		106·1 ± 13·1	
'Histalog' only (8)	16·2 ± 2·5	$P > 0.10$	132·5 ± 10·3	$P > 0.60$
Carrageenin + 'Histalog' (10)	14·0 ± 3·5		134·6 ± 8·0	

Carrageenin markedly reduces the volume and total acid concentration of the gastric juice secreted in response to histamine. How it produces this effect is not known. It may be that it renders histamine inactive by forming a complex with histamine as in the case of heparin[2], which is also a sulphated polysaccharide. By the use of 'Histalog' it has, however, been possible to establish that carrageenin does not directly interfere with the acid secretory mechanism. These results are of interest in relation to the role of histamine in gastric secretion.

We thank Dr. G. B. Shirlaw of Laboratories Glaxo-Evans, Paris, for supplying degraded carrageenin ('Ebimar'), and Dr. E. A. G. Cook of Ely Lilly and Co., Basingstoke, for supplies of 'Histalog'.

HAEMATOLOGY

Enhancement of the Activity of Optimum Concentrations of Urokinase by the Venom of *Echis carinata*

THE venom of *Echis carinata* (saw-scaled or carpet viper) is known to have powerful haemotoxic actions, promoting coagulation in whole blood or plasma and digesting fibrin[1]. We have recently investigated the action of this venom on the fibrinolytic enzyme system using the caseinolytic assay system of Remmert and Cohen[2] as modified by Alkjaersig[3]. Urokinase (2,000 U/ml.) was substituted for streptokinase, and 0·1 molar phosphate buffer for acid and alkali. Results are expressed in casein units/ml. Where *Echis* venom was used, 0·5 ml. of a 1 mg/ml. solution of a desiccator-dried preparation reconstituted in 0·9 per cent saline was incorporated in the system in place of 0·5 ml. of the phosphate buffer used in the assay. Similarly, buffer was substituted for urokinase and plasminogen in the experiments in which these reagents were omitted.

Table 1. CASEINOLYTIC ASSAYS

Urokinase	Venom	Plasminogen	Casein units/ml.
+	−	+	1·7 ± 0·3
+	+	+	5·1 ± 0·4
−	+	+	2·9 ± 0·2
−	−	+	0·5 ± 0·1
−	+	−	2·0 ± 0·1

The results are shown in Table 1, which presents the mean values and standard deviations for seven assays performed in duplicate. It will be seen that the venom of *Echis carinata* has direct caseinolytic activity (2·0 ± 0·1 units of activity); it also has the ability to produce partial activation of plasminogen, the increase in proteolytic activity of a venom-plasminogen mixture compared with venom alone being 0·4 ± 0·2 units ($t = 6.28$, $P < 0.001$). This compares with an activation of 1·7 ± 0·3 units produced by urokinase, due allowance being made in all cases for the spontaneous activity of plasminogen (0·5 ± 0·1 units). Of more importance, however, the results also show that the venom can augment the activity of an optimum concentration (2,000 U/ml.) of urokinase as a plasminogen activator, the activity produced by incubation together of urokinase, venom and plasminogen being 5·1 ± 0·4 U/ml., this being 1·4 ± 0·3 U more than that to be anticipated from the separate incubation of venom and plasminogen/urokinase with casein ($t = 11.96$, $P < 0.001$).

It has also been shown that the venom does not augment the activity of spontaneously activated plasmin and it would therefore appear that the augmentation of caseinolytic activity results from an action of the venom on plasminogen or on urokinase; but as incubation of venom and urokinase results in striking loss of urokinase activity it would seem probable that the venom acts directly on plasminogen. It may be that the action of the venom on the plasminogen molecule is to produce an alteration in its tertiary structure so that more arginine and lysine bonds are made available to attack by urokinase.

The inhibitor of plasminogen activation (ε-aminocaproic acid) has been added to the system but has no effect on the ability of the venom to augment plasminogen activation by urokinase. However, addition of a specific antivenom (Behringwerke A.G.) to the test system results in inhibition of proteolytic activity, plasminogen activation and also augmentation of the action of urokinase.

If the fraction of the venom which produces this unique effect can be isolated from the coagulant fraction it may have an important place in thrombolytic therapy as an adjuvant to urokinase and streptokinase, producing

augmentation of thrombolytic activity and thus accelerated vascular clearing.

Further investigation of the phenomenon may make available more detailed knowledge of the mechanism of plasminogen activation.

Plasminogen, streptokinase and ε-aminocaproic acid were provided by Dr. Hans Dahlstrom of A. B. Kabi, Stockholm, and urokinase by Dr. R. Herting of Abbott Laboratories, Illinois. The work was supported financially by the Ministry of Overseas Development, Ministry of Health, Kenya, and Merck, Sharp and Dohme Research Laboratories (Dr. M. Tishler).

BIOLOGY

Caulerpicin, a Toxic Constituent of *Caulerpa*

IT has long been known that the marine green alga *Caulerpa* has a peppery taste. Yet varieties of this species are used as a salad delicacy in the Philippines and lack it. We have attempted to discover the nature of the flavour-giving substance, having in mind its recognition for chemotaxonomic purposes. One of us (G. A.-S.) was able to obtain from ether extracts adsorbed on and then eluted from alumina crystalline material which melts at 95° C. We have named this material "caulerpicin". Mass spectrometry [illegible] that caulerpicin has a molecular weight of 649 with a possible formula of $C_{43}H_{87}O_2N$ and properties unlike those of any other compound of which we are aware. The infra-red spectrum indicates that caulerpicin may be a long-chain saturated hydroxy amide. So far it has been found in several *Caulerpa* species or varieties in different concentrations; as much as 600 mg have been isolated from 1,500 g dry weight of one variety of *Caulerpa racemosa* (Forsskal) J. Agardh.

Different people respond differently to caulerpicin. Some merely obtain a mild anaesthetizing sensation which is not immediate but is delayed for a minute or two. Others also obtain a numbness of the tongue or lips. In one subject exposed to the substance at various times truly toxic symptoms have become stronger and stronger following each contact. Almost immediately on chewing the raw dried *Caulerpa* material, the subject felt a numbness at the tip of the tongue. This has developed to a point at which the reaction is one of numbness of the extremities coupled with a cold sensation in the feet and fingers, rapid and difficult breathing, slight depression and, finally, loss of balance requiring the subject to lie down. The symptoms wear off, depending on the dosage, in a few hours to a day. Coupled with these reactions to the impure and pure substance, the same subject has developed a sensitivity to oysters and crabs and eating them produces the same symptoms.

The toxic effects are somewhat similar to those reported[1] for ciguatera fish poisoning in the Tropical Pacific. According to Banner's investigations ciguatera poisoning is caused most frequently by eating the red snapper (*Lutjanus bohar* Forsskal) which in turn feeds on herbivorous acanthurids such as *Acanthurus triostegus* Linnaeus. Dawson *et al.*[2] reported that *Caulerpa serrulata* (Forsskal) J. Agardh was found in the alimentary tracts of reef fishes from Palmyra Island in the Central Pacific. One of these, *Arothron hispidus* Linnaeus, was found to be poisonous; another, *Acanthurus triostegus*, is often poisonous.

In so far as we have been able to determine from Banner and Helfrich[3] and from questioning, ciguatera is unknown in the Philippines, although it is widespread in the Tropical Pacific. However, it is possible that the toxic response to shellfish on the part of our subject in the Philippines was due to substances such as caulerpicin being passed to the human food organisms, oysters and crabs, through a detritus food chain rather than through the herbivore fish to carnivorous fish food chain. We do not believe the effects of caulerpicin which we observed to be identical to those of ciguatera, but there is little information on this point.

The fishes and algae mentioned are common and generally distributed throughout the Philippines. Forsskal's authorship of so many of their names is an indication of their abundance and presence at the Red Sea end of their general biogeographic distribution across the Pacific. Since *Caulerpa* is a genus very widely spread in the tropics and also occurs in cold water in South Australia, for example, it would seem that if it is related to fish poisoning this would already be known. That *Caulerpa* is not so conspicuous a genus in the Eastern Pacific and perhaps the Eastern Atlantic as it is in the western reaches of these same oceans, may account for the lack of literature on this subject. We would appreciate any information relating *Caulerpa* to toxicity in marine products or to food chains either as detritus or directly-grazed material.

The field work for this project was supported in part by contracts with the U.S. Office of Naval Research and the U.S. Atomic Energy Commission.

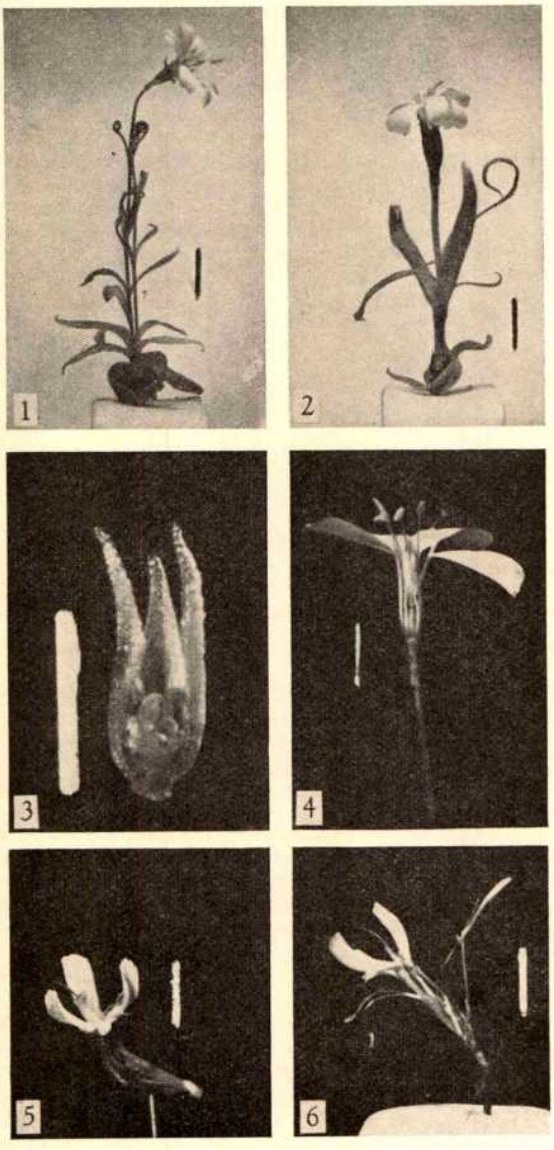
Flower Apices cultured *in vitro*



ALTHOUGH there are numerous reports dealing with the culture of plant tissues *in vitro*, there have been few successful attempts to culture isolated flower primordia. A suitable technique would, however, be valuable for many morphogenetic investigations, and therefore attempts have been made to culture buds of two species of *Viscaria*.

Dissection of flower apices was carried out by aseptic methods which yielded sterile cultures without difficulty. The excised apex was placed on a filter paper bridge[1] dipping into liquid nutrient medium in a 1 in. diameter 'Monax' tube covered with polypropylene film. The cultures were grown at 24° C under a 16 h daylength at an intensity of about 600 lumens per sq. ft. The nutrient medium was based on that of Murashige and Skoog[2]; the concentrations of the major elements and the ferrous sulphate–ethylenediamine tetraacetic acid (EDTA) complex were those recommended and, of the minor elements, one-tenth of those quoted. Other constituents (of which some were derived from Goodwin[3] and some from Vasil[4]) were as follows (quantities per litre); sucrose, 20 g; coconut milk, 100 ml.; casein hydrolysate, 1 g; inositol,

100 mg; cysteine, 5 mg; ribonucleic acid, 25 mg; kinetin, 1 mg; 8-OH-quinoline, 0·3 mg; EDTA, 37·3 mg; thiamine, 4 mg; nicotinic acid, pyridoxine, calcium pantothenate, riboflavine, biotin, choline, L-ascorbic acid, adenine and menadione, all at 1 mg; gibberellic acid and β-indolyl-3-acetic acid, both at 1 mg. The medium was adjusted to *p*H 5·7–5·8 and autoclaved.

Two long-day plants, *Viscaria candida* and *V. cardinalis*, have been used in this study. Both species flowered with from seven to ten pairs of leaves under continuous long day conditions and remained vegetative almost indefinitely under short day conditions. About 15 long days were required for full induction of flowering.

When vegetative apices about 1 mm in size were taken with one or two pairs of leaf primordia and grown under long days, they generally grew without rooting for a considerable time, and flowered after producing about the same number of leaves as a pot-grown plant. The flowers in such cultures were normal in all parts (Fig. 1).

Figs. 1–6. (1) Growth from a 1 mm vegetative apex after 10 weeks (scale equals 5 mm). (2) Growth after 5 weeks from a 500μ apex excised after minimal photoinduction (scale equals 5 mm). (3) State of flower bud when excised at 1–2 mm (scale equals 1 mm). (4) Normal flower (with calyx, two petals and one stamen removed) grown on plant under the same conditions as the cultured flower in Fig. 5 (scale equals 5 mm). (5) Flower cultured from a 2 mm bud, photographed 18 days after excision (scale equals 5 mm). (6) As Fig. 5, with calyx removed to show stamens and ovary (scale equals 5 mm).

Apices removed from plants which had received minimal photo-induction sometimes developed vegetatively and sometimes formed flowers when placed in culture. Fig. 2 shows a culture grown from an explant taken at 500μ in size with three leaf primordia. A further pair of leaves was laid down in culture followed by a full set of flower primordia, which developed normally in all respects.

If an apex were excised with sepal primordia only, or with petal and sepal primordia, the succeeding flower parts were all initiated and no treatment has so far disturbed the normal sequence. With such small apices, however, full development of the flower to maturity rarely occurred unless a pair of leaves was present. When buds were taken without leaves but with all parts just initiated (that is, at 500μ–2,000μ in size) normal development of the flower parts occurred (Figs. 5 and 6). In buds of less than 2 mm the calyx was well developed, the petals very small and the ovary at an early stage of initiation in the centre of the bud (Fig. 3). The stamens were the most advanced, but archesporial tissue was not differentiated in the anthers. In the complex medium used in this study normal growth of calyx, ovary and ovules was usually obtained. Petals were pigmented and fairly normal in shape, but sometimes they tended to be rather strap-shaped and sometimes lacked a corona. Stamen development was variable; in many cases normal development occurred and up to 50 per cent of the cultures produced one or more (sometimes ten) stamens with pollen which was sculptured and stained with acetic-orcein. Larger buds taken at 4–5 mm and containing pre-meiotic archesporial tissue tended to produce pollen more easily. The stamen filaments sometimes elongated normally but were often much reduced in length, though this also tends to occur in normal flowers grown at 24° C (Fig. 4).

This work has shown that cultures grown with leaves generally produced normal flowers, as Baldev[5], Chailakhian[6] and Raghavan and Jacobs[7] have also observed, the latter obtaining some viable seed. In previous work, culture of flower buds without leaves has proved more difficult. Tepfer[8] did not obtain development unless the calyx was removed; he did not achieve normal stamen development[9] and was unable to take a flower bud from the early stages of initiation through to maturity and flower opening. Galun[10] obtained ovary development in the cucumber, but he did not obtain[11] satisfactory stamen development. The complex medium used in this investigation has enabled flower buds to be grown without leaves from the early stages of initiation to maturity. Meiosis has been shown to occur in the stamens, and normal pollen and ovules have frequently been produced. Work is proceeding to reduce the complexity of the nutrient medium and define the conditions under which a fully normal flower is developed.

I thank Prof. J. Heslop-Harrison for his help. The polypropylene film was kindly provided by British Visqueen, Ltd.

A Culture Method of growing *Entamoeba histolytica* and Other Anaerobic Amoebae for the Study of their Nuclear Division

THE mode of nuclear division in *Entamoeba histolytica* and other anaerobic amoebae is not clearly understood. There are two main reasons for this: first, difficulty is encountered in obtaining the various normal stages of nuclear division; second, unsuitable cytological techniques are used to distinguish between chromatic and non-chromatic substances. Dobell[1] developed a culture method of obtaining large numbers of *E. histolytica* trophozoites in an actively growing condition. He grew amoebae by the Boeck–Drbohlav technique in a tube into which a coverglass was placed. The amoebae crept over the coverglass, where they continued their development, fed on the accompanying bacteria and rice starch and multiplied. Because they adhered to the glass, they could be readily obtained from the culture by removing the coverglass, and then fixed and stained. It should be emphasized that by this method large numbers of bacteria and rice starch particles also remain attached to the coverglass. This makes any study of nuclear structure and nuclear division difficult.

Singh[2,3] developed a method for the culture of small free-living amoebae; this enabled him to obtain without any difficulty all stages of nuclear division in nine species of amoebae. The amoebae were grown on thin films of non-nutrient agar on slides. They were then fixed according to normal cytological methods and the slides brought to water. At this stage the film of agar was removed by giving the slide a gentle shake in water; this left the majority of the amoebae attached to the slide.

The agar film culture method of Singh[2] has been modified to provide large numbers of trophozoites of *E. histolytica*, *E. invadens* and *E. moshkovskii* in a normal and actively growing condition. Thin films of non-nutrient agar (0·8–1·0 per cent agar depending on the quality of agar; 0·85 per cent sodium chloride) were made on coverslips. One or two small drops of hot melted agar were placed on 22 × 22 mm number '0' coverslips and quickly covered by round coverslips (16–18 mm diameter). When the agar had solidified, the top coverslip was gently pushed from one side and removed, leaving the film of agar on the lower coverslip. The films were kept in moist Petri dishes until required.

Twenty-four to forty-eight hour old amoebae growing in modified Boeck and Drbohlav medium (M/40 phosphate buffer in 0·85 per cent sodium chloride was used to dilute inactivated horse serum 1/7; *p*H 7·2) with mixed bacterial flora and rice starch were pooled and inoculated in large numbers in hollow ground slides (ground glass slides with a circular cavity 16 mm in diameter and 4 mm deep). The cavities were filled with diluted horse serum and a small quantity of rice starch (Difco) was added. They were then sealed with coverslips containing agar films, keeping the film downwards. Care was taken to avoid air bubbles. Any extra fluid around the coverslip was removed by filter paper. The cavity slides were then inverted and incubated at 37° C. There was profuse growth of amoebae on the agar films. After various intervals of time, ranging from 16 h to 24 h, the slides were inverted and the coverslips with the films gently removed with a pair of forceps. The amoebae were quickly fixed in Carnoy's solution (absolute alcohol six parts, chloroform 3 parts and glacial acetic acid one part) for 30–45 min. They were then placed in 90 per cent alcohol for 24 h and gradually brought to water. At this stage the films were gently detached around the periphery with a fine needle and removed by gently shaking the coverslips in water. The majority of the amoebae remained attached to the coverslips, and were stained with iron alum haematoxylin. It seems that amoebae sink through the agar, as observed by Singh[2] in the case of free-living amoebae, and remain adhered to the glass after the film has been removed.

It is hoped that by this method it will be possible to find normal, young and actively dividing amoebae. As the amoebae are confined to a small area, it should be easy to locate dividing individuals under an oil-immersion lens. The amoebae can be stained by suitable techniques so as to show up the chromatanic and non-chromatanic substances at various stages in the nuclear division.

Shaffer[4] has recently shown that the trophozoites of *E. histolytica* in Shaffer–Frye or CLG medium[5] possess two or more nuclei. From 2 to 25 per cent of the amoebae were binucleate between 8 h and 16 h and continued for 120 h of incubation. No binucleate amoebae were present at 4 h or 8 h of incubation. A few trophozoites which contained from three to five nuclei were found without any apparent relation to the growth cycle of the culture. Based on these observations, Shaffer[4] has suggested that nuclear division and cell division may be separate phenomena that do not necessarily proceed in parallel.

We have found that on a single coverslip preparation made from 16–24 h old cultures of *E. histolytica* and *E. invadens* there were plenty of trophozoites with two or three nuclei. Amoebae with four or five nuclei were less frequent. Amoebae containing six, seven and eight nuclei have also been observed; multinucleate amoebae also occurred with *E. moshkovskii*. The nuclei and cell cytoplasm in multinucleate *E. histolytica*, *E. invadens* and *E. moshkovskii* appeared to be quite normal. Our observations support Shaffer's[4] suggestion that nuclear and cell division are probably two separate phenomena.

We thank Dr. B. N. Singh, head of the Division of Microbiology, for suggesting the problem and for helpful advice.

Effect of Spinal Lesions on the Colour Change of the Minnow (*Phoxinus phoxinus* L.)

THE dorsal and lateral surfaces of the minnow (*Phoxinus phoxinus* L.) change colour on pale and dark backgrounds. This colour change is effected by changes in the condition of the melanophores which are found on these surfaces of the minnow. Large macromelanophores and small micromelanophores can be seen under the binocular microscope, and the differential distribution of these two types gives rise to a prominent pattern which is to be observed particularly during the paling and darkening of the fish. Black-adapted minnows taken from a black background and placed on a white one pale rapidly during the first few minutes under nervous control, then continue to pale at a slower rate under hormonal control[1]—maximum pallor is reached after some hours. The macromelanophore pattern pales more slowly than the micromelanophores and it is still visible after the fish has been paling for one minute but has more or less disappeared after 3 min. On a black background the fish darkens rapidly during the first few minutes and maximum darkness is attained after some hours.

A melanophore aggregating centre exists in the medulla oblongata of the minnow from which autonomic pigmentomotor fibres pass caudally to their spinal outflow levels

and then pass cephalically and caudally along the sympathetic chain and innervate the melanophores by means of the spinal and trigeminal nerves[2]. The spinal pigmento-motor fibres are located dorsomedially within the tissues which include the substantia gelatinosa Rolandi and the dorsal part of the corpus commune posterius[3,4].

Kappers *et al.*[5] claimed that knowledge of the sympathetic nervous system of fish was very meagre especially in regard to finer details. This still holds to-day for the spinal autonomic tracts. The experiments described here are concerned with the effect on the colour responses of cutting a proportion of the spinal pigmento-motor fibres.

Lesions were placed ventrally, dorsally and laterally by means of micro-dissection instruments at vertebrae 3–4 and 10–11 and at the spinal outflow levels between vertebrae 12 and 14 (refs. 3 and 4) in different fish. The colour responses to black and white backgrounds were tested after the fish had recovered from anaesthesia and compared with their pre-operational colour responses. The extent of each lesion was determined histologically from serial sections stained with Mallory's trichrome.

The effect on the colour responses of lesions placed at vertebrae 3–4 and at vertebrae 10–11 depended on whether the dorsomedial spinal tissues at these levels were damaged. Total destruction of these tissues eliminated the rapid, neurally controlled colour responses of the fish to different backgrounds whereas the colour responses were unaffected if the dorsomedial tissues were intact. Partial damage to the dorsomedial tissues at these levels resulted in a prominent dark mottled pattern which was distributed over the dorsal and lateral surfaces of the fish and was observed when the fish were allowed to pale on a white background. This pattern appeared to arise from a differential behaviour of the melanophores and it persisted when the fish was left on a white background for 3 min.

This effect was observed in fifteen fish in which spinal lesions had been placed at vertebrae 3–4 or 10–11 and in all cases there was appreciable damage to the dorsomedial tissues, but there was no correlation between the development of this pattern and the aspect of the lesion. In particular, dextral and sinistral hemisections did not result in a unilateral response but produced a similar bilaterally distributed mottled pattern.

A similar mottled pattern was observed in eighteen minnows in which spinal lesions were placed between vertebrae 12 and 14. At these levels there appears to be no correlation between the extent of the lesion and its effect. The results seem to indicate that at these levels the spinal pigmento-motor fibres run ventrally from the dorsomedial spinal tissues and are widely dispersed throughout the cross-sectional area of the spinal cord. Furthermore, lesions placed in the posterior part of the outflow region, that is at vertebrae 13 and 14, did not affect the colour response of only the caudal region of the fish but, instead, a mottled pattern completely covering the dorsal and lateral surfaces was observed, thus indicating that pigmento-motor fibres from these spinal levels run both cephalically and caudally along the sympathetic chain. The macromelanophores of the lateral stripes and of the dorsolateral pattern appear to be more readily affected by damage to the pigmento-motor fibres than the micromelanophores, but, in spite of this, the post-operational mottled pattern has a somewhat different appearance from the pre-operational macromelanophore pattern which is observed during paling and the precise nature of the post-operational mottled pattern is worthy of further investigation.

The mottled pattern in some of the specimens was examined under the binocular microscope by means of a method adapted from that described by Hogben and Slome[6] and Healey[1]. Some of the melanophores showed asymmetrical dispersion and it is suggested that this observation supports the conclusion of Gray[7,8] that individual melanophores are innervated by more than one neurone. Thus the asymmetrical response would indicate that some of the melanophore innervating fibres are associated with spinal pigmento-motor fibres which have been cut while other fibres innervating the same melanophore were associated with intact spinal pigmento-motor fibres.

It is suggested, on the basis of the observations described here, that cutting a proportion of the spinal pigmento-motor fibres results in a differential behaviour of the melanophores in response to background reversals from a black to a white background. It would appear that the fibres of any specific region of the spinal pigmento-motor tract are associated with melanophore innervating fibres having a wide cutaneous distribution. It is also tentatively suggested that postganglionic melanophore innervating fibres retain their individual integrity rather than form a continuous diffuse cutaneous nerve net. This latter suggestion requires substantiation by a closer study of the precise nature of the post-operational melanophore pattern and further study of melanophores as effectors.

This investigation was conducted under the supervision of Dr. E. G. Healey during the tenure of a Department of Scientific and Industrial Research studentship.

Relation of Temperature to the Duration of the Development of Insects

THE relationship between temperature and the mean hatching time of eggs is of the same pattern for most insect species. The mean hatching time decreases as the temperature increases until the so-called peak temperature is reached; this is the temperature at which the mean hatching time attains its minimal value. At temperatures above the peak, the observed mean hatching time increases with increasing temperature.

The majority of the attempts that have been made to give a mathematical description of this relationship represent the hatching time as undergoing a steady decrease with increasing temperature; the data at temperatures above the peak are ignored. A noteworthy and invariable feature of the experiments is the increase in the proportion of eggs which fail to hatch at temperatures above the peak. It is my conjecture that the temperature–hatching time relationship estimated from experimental data is distorted by a bias introduced by the high mortality at high temperatures. This bias may be so large as to explain the increase in hatching time at temperatures above the peak.

Although the cause of death at high temperatures is unknown, it probably results, not from the direct action of heat, but from an upset in the balance of some metabolic process[1]. As the temperature rises, the metabolism of the egg increases; the extra energy which results is expended on accelerating the period of development. At some point the metabolic processes break down and the egg fails to develop. It is probably this factor—the breakdown of metabolism—that is the direct cause of death. The effect of temperature on survival is merely indirect by making the rate of metabolism fall within the limits of tolerance.

It is plausible to infer from this description of growth and mortality that eggs developing at the same metabolic rate have a common hatching time and a common survival rate; the hatching time and survival rate both decrease with increasing metabolism. Because metabolism increases with increasing temperature, the model outlined here is apparently at variance with the increase in mean hatching time at high temperatures observed in experimental work. The explanation for this apparent disagreement can be found in the wide variability in hatching times of individual eggs kept at the same constant temperature. A typical instance of this variability is provided by Stanley's data[2] on hatching times of the eggs of *Tribolium confusum* maintained at 28° C; the smoothed frequency distribution is shown in Fig. 1; it has a mean of 143 h and a range extending from 129 h to 226 h. Stanley obtained data which had distributions of the same shape and order of variability, but with progressively smaller means (at 29° C, 31° C and 33° C). The high mortality at 35° C left too few successful hatchings on which to base a smoothed distribution. The effect of increases in temperature is to shift the distribution of hatching times progressively towards the left until the point at which mortality begins to operate. At this point, the individuals on the left of the distribution (those with the more rapid development and shorter hatching time) suffer a higher rate of mortality than those with longer hatching times. Consequently the mean hatching time of the survivors is greater than that which would have been obtained if there had been no mortality; thus the relationship between the observed mean hatching time and temperature does not follow the same pattern as that between the inherent hatching time of an individual egg and temperature. In the former case the observed mean is greater than the theoretical one. As the mortality progressively increases beyond the peak value and only the individuals in the long tail of the skew distribution hatch successfully, the divergence between the observed mean and the theoretical value becomes larger.

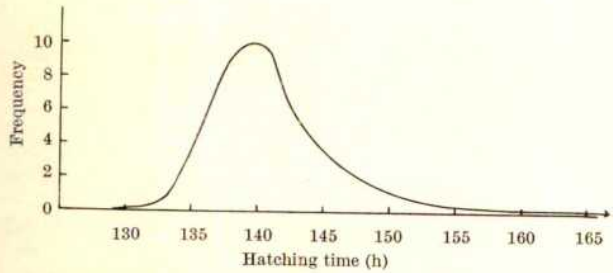

Fig. 1. Smoothed distribution of hatching times of *Tribolium confusum* eggs kept at 28° C. Data from Stanley (ref. 2).

Even if the inherent hatching times of individual eggs continue to decrease with increasing temperature up to the point of death, provided that the degree of skewness of the distribution is sufficiently pronounced, the observed mean hatching time may well show an increase at high temperatures.

As yet no assessment can be made of the validity of this conjectural description of egg development; because of the heavy mortality at high temperatures, the data available are insufficient to provide a basis for criticism. A clear picture can only be obtained from a much larger number of data.

Chromosomes of the Coypu

THE coypu, *Myocastor coypus* Molina (or *Myopotamus coypus*, *Myopotamus bonariensis* Commers, *Hydromys coypus* Geoff.), is a South American rodent that belongs to the family Octodentidae and sub-family Capromyidae. To-day it is found in all continents, living in swamps and fish ponds as a feral animal or raised in captivity for its fur[1]. So far as we know, no previous investigation of chromosome number and morphology has been carried out on this animal.

This communication reports the observations we made on number and morphology of the chromosomes in the coypu using the bone marrow tissue culture method. Preparations of cultures from both sexes were analysed. The diploid chromosome number of the coypu, belonging to the standard brown type, was found to be forty-two ($n = 21$).

Several methods for preparing cells were tested including the aceto orcein treatment of testes[3], the cornea method[4,5] and the phytohaemagglutinin blood culture[6]. For unknown reasons the last method failed to give any mitoses. A modified form of the bone marrow culture method[6] was found to give the best results. Three animals, one male and two females, belonging to the farm-bred standard brown type were used. Each animal was injected intraperitoneally with 0·2 ml. of 0·1 per cent 'Colcemid' solution. After 3 h the animal was killed by an overdosage of 'Nembutal' (10 ml.) and the femurs were immediately dissected out. The epiphyses were cut off and the marrow was washed out with warm (37° C)

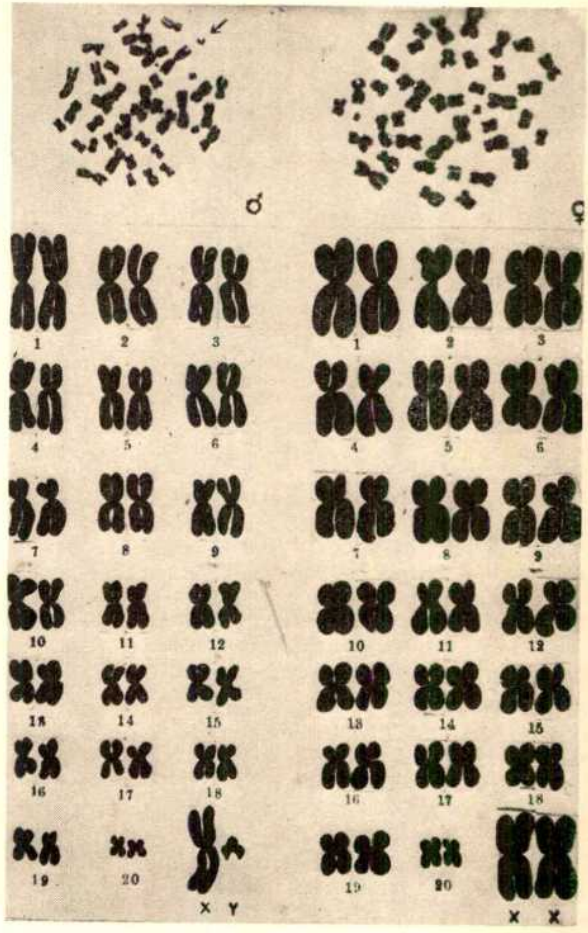

Fig. 1. Coypu karyograms. Male karyogram on the left and female on the right. In the upper left corner the Y chromosome is marked by an arrow. The original photos are magnified × 378, and the chromosomes have been arranged according to their size and the position of the centromere.

1 per cent sodium citrate solution. After 30 min the cells were centrifuged at 700 r.p.m. for 10 min, the supernatant removed and 3 ml. of fixative (three parts absolute alcohol to one part glacial acetic acid) was carefully added, so that the cells were suspended in it. After 10 min the material was centrifuged at 400 r.p.m. for 5 min, the supernatant was removed except for one drop in which the cells were re-suspended, and freshly prepared fixative was added. Slides were immersed in 20 per cent ethanol and after 2–3 drops of the suspension had been pipetted on to each one, they were heated over a flame for a few seconds. The cells were stained with 'Giemsa' solution.

By this method we were able to obtain two hundred cells in mitotic metaphase suitable for analysis. From the counts it was found that the number of chromosomes in the coypu is forty-two ($n = 21$). Very few deviations from this number were observed, and these were most probably the result of technical errors. A few polyploid cells were also observed.

In typical cells (Fig. 1), out of 21 pairs there is one very large (No. 1) and one very small (No. 20). The rest of the chromosomes are a continuous range of sizes between these two extremes. The two X's are second to largest and the Y is the smallest but one. The only telocentric chromosome is the Y chromosome. The chromosomes of pairs Nos. 1, 2, 10, 13, 14, 17 and 18 can be considered metacentric and the remainder sub-metacentric. No chromosomes with satellites were observed.

RADIOBIOLOGY

Correlation of Lead-210 with Strontium-90 in Human Bones

THE radioactive gas radon-222, produced by the decay of radium-226, diffuses from the ground and is transported by atmospheric turbulence far from its origin through the troposphere and into the stratosphere[1]. The radioactive decay of radon-222 and its short-lived descendants produces measurable quantities of lead-210 in the atmosphere[1–3]. Lead atoms so formed become attached to dust particles and eventually return to the Earth's surface, principally in rainfall[1,4,5]. Hill's[4] report of a correlation coefficient of 0·87 between the quantity of rainfall and the concentration of lead-210 in grass clearly indicates a linear relationship. Holtzman[6] reported a relationship between the concentration of lead-210 in the human skeleton and in the atmosphere. Whether the lead-210 enters the body principally through precipitation on foodstuffs that are later eaten[5] or through direct inhalation, or by both means[7], is at present uncertain. It is therefore feasible to view the occurrence of lead-210 as a "natural fall-out" product, similar, in this respect, to fission product fall-out, artificially produced from a nuclear detonation. In fact, very strong similarities between lead-210 and fission product activities have been reported with respect to their behaviour in the atmosphere[1], to their rate and mode of deposition[1,5], and to their concentration in grasses[4]. The similarities between lead-210 and fission product activities do not imply any relationship in their production. The formation of lead-210 in nuclear weapons explosions is improbable, and if any were so formed it would be negligible in comparison with the amount formed by natural processes[8]. The observed similarities between lead-210 and fall-out are caused by their similar behaviour in the atmosphere.

When lead or strontium is ingested, it is deposited predominantly in the skeleton. Thus, a correlation may exist in the human skeleton between lead-210 and strontium-90, a long-lived fission product. To investigate this possibility, we analysed for lead-210 samples of vertebra from fourteen infant children residing in the Cincinnati, Ohio, area, who died at the ages of 3 days to 12 months. The strontium-90 concentrations were determined at the U.S. Public Health Service, Northeastern Radiological Health Laboratory in Winchester, Massachusetts, and have been published[9]. The lead-210 content in the bone samples was determined by dissolving a 5 to 10 g sample of bone ash in 0·1 N hydrochloric acid, depositing the polonium-210 from the sample on a 1–0·5-in. diameter polished nickel planchet[10,11]. The lead-210 activity was then calculated from the polonium-210 α-activity after correction for incomplete polonium-210 ingrowth had been made. The calcium content of the bone samples was obtained by precipitating the calcium as the oxalate with oxalic acid at a pH of 2·5–3, dissolving the precipitate in sulphuric acid and titrating the calcium with a standardized solution of potassium permanganate[12]. The results are given in Table 1. The uncertainty in the lead-210 and strontium values, calculated for a one standard deviation counting error, is 5 and 6 per cent, respectively. The average lead-210 and strontium-90 concentrations in these skeletal samples are 0·133 and 2·19 pc./g calcium, respectively. The average lead-210/strontium-90 ratio was 0·068. The vertebra of the 3 day old infants contained lower concentrations of both lead-210 and strontium-90, but the ratios of the two nuclides were high in all three cases. These concentrations probably reflect contributions from the mother during pregnancy, and may imply less placental discrimination against lead than against strontium.

* ^{90}Sr values from *Radiat. Health Data*, **5**, 620 (1964).

In Fig. 1 the lead-210 concentrations are plotted against the strontium-90 concentrations in pc./g calcium. A linear relationship is clearly suggested. The value of the linear correlation coefficient here was determined as 0·89. Such a strong correlation lends support to the hypothesis that lead-210 is an airborne contaminant, and

is related to fission product fall-out through its similar behaviour in the atmosphere. The fact that these samples were obtained from residents of a limited age group in one area, who subsisted on similar foods (primarily milk), was without doubt partially responsible for the observed correlation. The principal source of strontium in children is milk, which is concentrated by the cow from a diet consisting mainly of grass. Because a strong relationship has been reported between strontium-90 and lead-210 in grass, and because cows' milk has been observed to reflect lead uptake by the cow[13], this correlation between strontium-90 and lead-210 in infants is to be expected.

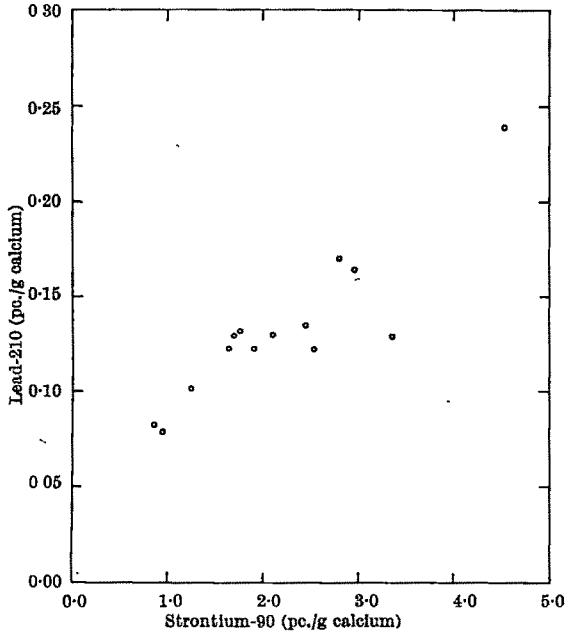

Fig. 1. Concentration of lead-210 versus strontium-90 in bones of infants from Cincinnati, Ohio.

Lead-210 and strontium-90 concentrations were also obtained for a set of eighteen vertebra samples of persons between 5 and 22 years of age who had resided in New Hampshire, Vermont and Massachusetts. For this set of samples the linear correlation coefficient was calculated to be 0·67. Although the linear correlation is not nearly so satisfactory as that found for the infant samples, a linear relationship is recognizable. The varied eating habits of the older group may be responsible for the smaller correlation. Persons of this age group consume a wide variety of foods grown in different localities, which undoubtedly contain different levels of strontium-90 because the distribution of fall-out from atmospheric nuclear tests is not uniform. Thus the fission product fall-out, following shortly after an atmospheric nuclear explosion, predominates over fall-out returning to ground from the stratosphere where a close lead-210 fission product relationship has been observed[1]. No correlation could be detected between lead-210 and radium-226 in our samples. A similar lack of correlation was reported by Holtzman[7]. The different distribution pattern of radium-226 and lead-210 in bone again indicates that lead-210 enters the environment as a product of fall-out, and is not related to its place of origin.

The relative dose to the infant bones delivered by lead-210 and strontium-90 can be calculated from the observed average activity ratio, 0·068. Because the principal dose contributed by the lead-210 to polonium-210 chain is delivered by polonium-210, the equilibrium that exists between lead-210 and polonium-210 in bone must be known. In conflict with the value of 0·1 for the polonium-210/lead-210 activity ratio in bone presented by Committee II of the International Commission on Radiological Protection[14], recent investigators have shown this value to be close to unity[7,15–18]. Assuming, therefore, that radioactive equilibrium exists in bone between lead-210 and polonium-210, and that there is a relative biological effectiveness (RBE) of 10 and a uniform distribution of lead-210 and strontium-90 within the bone, the dose delivered by lead-210 and daughter elements to these infant bones is 3·4 times that delivered by strontium-90 and its daughter, yttrium-90.

The results of this study indicate that a correlation exists between lead-210 and strontium-90 in the human skeleton, and also support the fall-out hypothesis which postulates contamination of the environment with lead-210. Furthermore, they demonstrate the similar behaviour of lead-210 and fission products in our environment, as noted in earlier reports. The relative dose, lead-210/strontium-90, delivered to the infant bones, based on the average lead-210/strontium-90 activity ratio, was calculated to be 3·4. If the nuclear test ban treaty continues, the lead-210/strontium-90 ratio observed in this study will increase because the lead-210 concentration should remain relatively constant while the strontium-90 concentration should slowly decrease.

I thank R. M. Hallisey, Northeastern Radiological Health Laboratory, for the bone samples used in this study, and B. Kahn, Radiological Health Research Activities, Robert A. Taft Sanitary Engineering Center, for advice.

Response to X-irradiation of a Tumour recurring after a TCD_{95} Radiation Dose

CHINESE hamster cells which survived 1,500 rads (a survival fraction of $\approx 2 \times 10^{-3}$) were found to have several heritable altered biological properties. These included a slower cell population doubling time, a smaller cell size, an abnormal chromosome number and morphology, and an increased radio-sensitivity—namely a D_0 value of $\approx$135 rads instead of the 205 rads for the unirradiated or control cell line. Furthermore, these characteristics persisted in a number of the sub-lines for many months of continuous culture[1]. That changes of this type should occur in cells of tissue irradiated *in vivo* is plausible, and if they do occur such alterations would have important implications for tumour radiobiology and for clinical radiotherapy. This report describes an initial experiment that was designed to test for such an effect.

A radiation dose–tumour control response was performed on second generation isotransplants of a *C3H* mouse mammary carcinoma growing in the subcutaneous tissue of the flank of *C3H* mice (female, mammary tumour agent positive); the carcinomata were about 70 mm³ at the time of irradiation. The tumours were treated with one of five dose levels (single dose treatment) and irradiation was administered under conditions of local tissue anoxia (for additional details, see refs. 2 and 3). The dose that yielded local control of tumour in half the treated lesions (TCD_{50}) was 5,990 rads at 240 days after treatment.

A recurrent tumour was noted in one of eight animals at 240 days following 6,600 rads, or a dose corresponding to TCD_{95}. This tumour was in the centre of the irradiated area, that is to say, it was not a marginal recurrence. It is highly probable that the lesion developed from a single surviving cell and, therefore, might be an *in vivo* counterpart of the "small colony" of Sinclair. This recurrent tumour had a volume doubling time of about 17 days as compared with 3–4 days for original unirradiated tumours. The small recurrent tumour (3 mm diameter) was excised and isotransplants were prepared. The resultant tumours also grew quite slowly and had reached a diameter of about 15 mm by 6 months. From this tissue, isotransplants were prepared using inbred animals from the same source as those used in the original dose response investigation. The "take rate" of the tumour transplant was 98 per cent for both series. For the original dose response assay, transplantation was made 24 h after the host animal had received 400 rads of total body irradiation. The investigation of which that assay was a part[2] showed that the TCD_{50} for tumours growing in animals which had received total body irradiation was similar to that for tumours in untreated animals, and also was the same as for autotransplants (all treatments given to 4 mm³ tumours and under conditions of local tissue anoxia). Because of those findings, the dose response assay of the recurrent tumour was made on tumour tissue transplanted into unirradiated mice.

Table 1. TCD_{50} VALUES FOR TUMOURS PREVIOUSLY UNIRRADIATED AND FOR TUMOURS RECURRENT FOLLOWING A TCD_{95} RADIATION DOSE. THE FIGURES INDICATE THE 95 PER CENT CONFIDENCE LIMITS AROUND THE TCD_{50} ESTIMATE

Previously unirradiated tumour	Recurrent tumour
TCD_{50} in rads at 240 days	TCD_{50} in rads at 240 days
5600 ... 5990 ... 6390	4800 ... 5130 ... 5480

The results of these experiments are given in Table 1, and show that the TCD_{50} at 240 days was significantly less for the recurrent lesion, that is, 5,080 rads instead of 5,990 rads.

The difference in TCD_{50} values was not so marked as it would have been had the change in D_0 been comparable with that observed by Sinclair. However, the *in vitro* investigations showed a gradual reversion toward the normal or control value with prolonged culture. The irradiation of the tumour tissue derived from the recurrent lesion occurred about 18 months following the treatment of the initial tumour. The results reported here suggest that the changes described by Sinclair for cells investigated *in vitro* may occur in cells of tumour tissue irradiated *in vivo*. Further and more detailed investigations of this effect are planned.

This investigation was supported by grants from the National Cancer Institute, National Institutes of Health, U.S. Public Health Service.

AGRICULTURE

Fleece Length and the Reactions of Sheep to Wet and Dry Heat

THE experiments of Lee[1] indicate that shearing sheep may, depending on climatic conditions, either increase or decrease the animal's reaction to heat, and that atmospheric temperature and humidity conditions can be divided into two distinct groups on this basis. This work has been confirmed by Klemm[2], whose results clearly demonstrate that shorn sheep tolerate hot wet atmospheres better than unshorn sheep, the reverse situation applying under hot dry conditions. In view of these differences, it was of interest to examine the influence of a range of fleece lengths on the reactions of sheep to wet and dry heat.

Ten 6 year old Merino wethers, each of which weighed 42·3–51·4 kg, were used in the experiment. The wethers were of a fine woolled strain and at appropriate intervals randomly selected pairs of them were shorn so that at the beginning of the experiment the range of fleece lengths shown in Table 1 was represented. During a pre-experimental period of 14 days, and when not in the hotroom, the sheep were housed indoors (temperature range: 9°–26° C) and communally fed a maintenance ration of equal parts lucerne chaff and concentrates at 5 p.m. daily. Drinking water was available *ad lib.* at all times except during hotroom exposure. During the pre-experimental period the animals were accustomed to the experimental conditions and procedures.

Table 1. INFLUENCE OF FLEECE LENGTH ON THE REACTIONS OF SHEEP TO HOT WET AND HOT DRY ATMOSPHERES

* Hours of exposure.
† Rectal temperature, °F.
‡ Respirations per mn.

Tests of the animals' reactions to hot wet (41·0° C, 30 mm mercury) and hot dry (41·0° C, 10 mm mercury) atmospheres were made over an 11 day period commencing on April 21, 1966. In all, four tests were made with each animal, two alternate exposures to both hot wet and hot dry conditions. To minimize acclimatization to heat, two full days were allowed between successive tests on each animal. One wether from each of the five pairs was tested one day and the remaining five animals the following day.

On each test day the five wethers to be used were placed in the preheated hotroom at 9.30 a.m. and remained there for 7 h or until their rectal temperature exceeded 41·7° C (107·0° F). Measurements of rectal temperature (by thermocouple inserted 4 in.) and respiratory rate (flank movements counted over two 30 sec intervals) were made immediately before the animals entered the hotroom and at hourly intervals during the subsequent exposure. In the interests of brevity, only the results from 0, 1, 3 and 6 h of exposure to test conditions are presented in Table 1. In all cases, however, these results are fully representative of the hourly recordings actually taken.

The results from exposure of the test wethers to a hot dry atmosphere substantiate previous reports[1,2] that such conditions are best tolerated by unshorn sheep. Further examination of the data in Table 1 reveals that, while there is a progressive decline in response with increasing fleece length, the animals may be divided into two distinct

groups according to their response to the hot dry conditions. Wethers with fleeces 0·5 and 1·0 cm long exhibited similar reactions and these were distinctly higher than those of wethers with a fleece length of 2, 4 or 8 cm. It would seem that a fleece about 2 cm long affords a substantial degree of insulation against a hot dry atmosphere in the absence of a radiant heat load, and that fleeces in excess of this length provide little additional protection. Under more severe conditions when radiant heating is superimposed on a hot dry atmosphere it has been shown[3,4] that 4 cm represents a similar critical fleece length.

Under the hot wet conditions used in this experiment, fleece length had no apparent effect on the heat tolerance of the test animals. The 30 mm mercury water vapour pressure used was dictated by the capabilities of the hot-room at the time of the experiment and, although not extremely high, could have been expected to elicit a fleece length effect on heat tolerance[2], especially with regard to respiratory rate. The fact that the superior heat tolerance which was exhibited by the woolly sheep under hot dry conditions is no longer apparent under the hot wet atmosphere suggests that the latter was, under the conditions of the experiment, only marginally wet.

Klemm[2] has attempted to explain the relative intolerance of unshorn sheep to hot wet atmospheres in terms of the hygroscopic properties of wool, the resultant exothermic reaction giving rise to a wool-skin temperature gradient. If this is so then *in vitro* studies with sheep skins which were carried out concurrently with the experiment described here add further weight to the suggestion that the hot wet atmosphere used was only marginally wet. These skins gained weight only very gradually when exposed to hot wet conditions. For example, a skin which clipping showed to carry a 7 cm fleece weighing 2·81 kg in the ante-room gained about 30 g during each of the first 2 h of exposure and only a further 40 g during the remaining 5 h.

Comparison of the results from the two test atmospheres illustrates the influence of humidity on heat tolerance in sheep and the ability of this species to tolerate all but the most severe environments.

Effect of Stocking Rate and Lambing Time on Gestation Length in Sheep

ALEXANDER[1] suggested that severe undernutrition of sheep may reduce the gestation length in sheep and he reported reductions of up to 3·6 days in gestation length in ewes transferred to a low plane of nutrition.

In an experiment varying stocking rate and lambing time[2], the length of gestation was recorded in a flock of 378 ewes over a three year period. In the extreme Mediterranean environment in which this work was carried out (Kojonup, Western Australia) the withholding of supplementary feed can result in severe nutritional stress to autumn (April–May) lambing ewes that are being depastured at a high stocking rate.

The mean gestation lengths for the several treatments in the 3 years of the experiment are shown in Table 1, while the liveweight of the ewes in relation to the number of days pregnant is shown in Fig. 1.

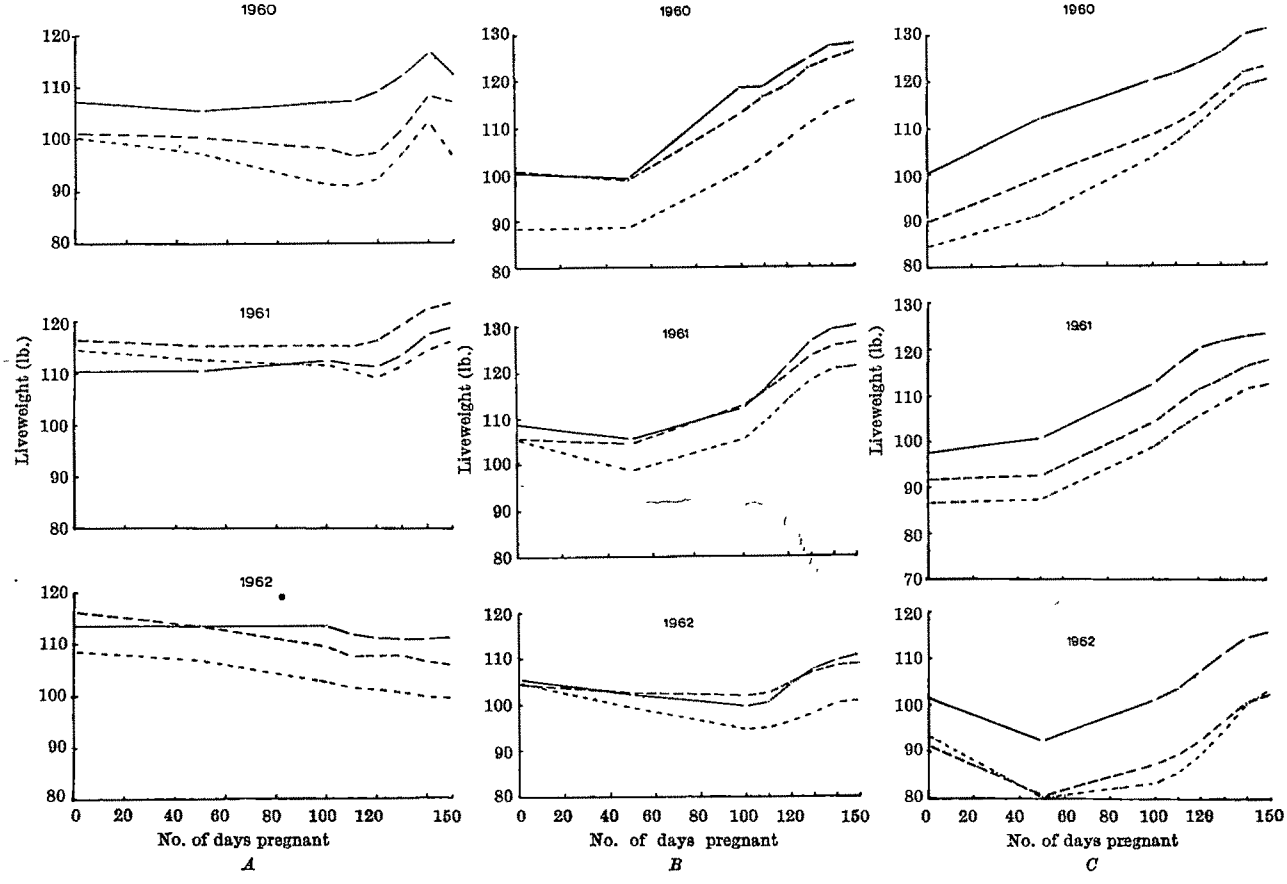

Fig. 1. Liveweight change of ewes in relation to number of days pregnant. *A*, Autumn lambing; *B*, winter lambing; *C*, spring lambing. ——, 1·5 ewes per acre; – – – –, 3·0 ewes per acre; — · — · —, 5·0 ewes per acre.

Table 1. MEAN DURATION OF GESTATION IN DAYS OF EWES LAMBING IN TIME AGAINST STOCKING RATE

(1960–1962)

Year	Lambing time	Mean gestation length Stocking rate 1·5	3·0	5·0

N.S., denotes $P > 0·05$.

Fig. 1 shows that the range of liveweight change during pregnancy was from a loss of 9·0 lb. (indicative of severe nutritional stress) to a gain of 29·0 lb. The range of liveweight changes obtained should be sufficient to determine the possible effect of nutrition on gestation length under field conditions. Although the greatest mean loss in weight for any treatment was 9 lb., individual sheep lost up to 20 lb.—a figure comparable with those of Alexander.

In the three seasons studied there were considerable differences in the pattern of liveweight change of the ewes in late pregnancy. Nevertheless, there was no evidence that gestation length was related to plane of nutrition. Twin lambs, of course, increase the nutritional stress of pregnancy[3]. In the present experiment, very few twin lambs were born, and in all cases gestation length was greater than 150 days.

The apparent effect of lambing time on gestation length in 1961, but not in the other seasons (as shown by the highly significant interaction in Table 1), needs explanation. It was thought that it might be accounted for by varying nutritional effects in the 3 years, of which maternal liveweight change during pregnancy could provide an index. The change from 100 to 140 days was accordingly used as the independent variable in an analysis of covariance of the gestation length data. The regression in the error term was not significant, and the effect of lambing time on gestation length in 1961 remained significant after a possible nutritional factor had been eliminated in this way. Climatic differences might provide a possible explanation.

No acceptable interpretation of the interaction of lambing time and stocking rate can be proffered.

The small and statistically non-significant difference of 0·6 days[4] in the gestation length of ewes bearing a single lamb on a high plane of nutrition compared with ewes bearing a single lamb on a low plane gives some support to the present findings.

The differences between our findings and those of Alexander are probably due to dissimilar experimental conditions. In Alexander's experiment, the under-nutrition was induced abruptly by giving different feed levels to ewes which before the experimental period had either been maintaining or gaining weight. In our case, where the ewes on the low plane of nutrition were kept continuously on the experimental plots, under-nutrition was prolonged, and became progressively more severe. Thus, when the plane of nutrition has been steadily and slowly deteriorating, insufficiency of foetal nutrition need not be a factor involved in the initiation of parturition as postulated by Spiegelberg[5].

When the plane of nutrition is deliberately reduced in middle or late pregnancy, as in the case reported by Alexander[1], then insufficient foetal nutrition may well reduce gestation length.

IMMUNOLOGY

Maintenance of Histocompatibility Polymorphisms

THE transplantation antigens present a striking example of genetic polymorphism. Medawar[1] has stated that "Although there are no factual grounds for supposing that antigenic diversity is anything but an unfortunate consequence of constitutional differences between individuals of a species, yet one is under some obligation to rack one's brains for evidence of any good it might conceivably do. Only thus can antigenic polymorphism be made genetically respectable". Because during gestation the foetus is a homograft to the mother and would therefore seem liable to rejection, this variability would at first sight appear to be a distinct disadvantage to a viviparous animal. The hypotheses put forward to account for the survival of the foetal homograft have recently been reviewed by Billingham[2]. Most of them have not withstood experimental verification, but there is good reason to believe that one, which assumes the presence of a physical barrier between mother and foetus, is correct[3,4]. Antigenic differences between mother and offspring are not, however, without effect; the consequences of blood-group incompatibility, for example, are well known. Recently, it has been shown that other antigenic differences may affect the growth of the placenta[5], and also the size of the foetus itself[6,7]. If one inbred strain of mice is mated with another, the hybrid foetus is significantly larger just before birth than a pure bred foetus of either parental strain. This increase in size does not arise from classical heterosis alone, as the effect can be enhanced by making the mother immune to the tissues of her partner or diminished by making her tolerant of them[6]. In these experiments it seems probable that the foetuses which are unlike their mothers, and therefore larger at birth, have a greater chance of survival. These observations suggest a system for maintaining balanced polymorphism; it can be represented by the following model.

We assume a random-mating population in which there are two alleles, H_1 and H_2, at frequencies p and q, respectively ($p + q = 1$). We consider that the reproductive abilities of the females of all three genotypes are equal, but that offspring against which the mother can form antibodies enjoy a selective advantage. We also assume that the frequencies of the three genotypes in each generation are approximately in Hardy–Weinberg equilibrium. Strictly, the last mentioned assumption is only valid if the selective differences between genotypes are small, but even large differences will not significantly alter our conclusions. The frequencies of matings and offspring are set out in Table 1. It can be seen that the heterozygote shows a net selective advantage over both homozygotes.

Table 1

Mating ♀	♂	Frequency of offspring H_1H_1	H_1H_2	H_2H_2
H_1H_1	× H_1H_1	p^4		
H_1H_1	× H_1H_2	p^3q	$p^3q(1+s)$	
H_1H_1	× H_2H_2		$p^2q^2(1+s)$	
H_1H_2	× H_1H_1	p^3q	p^3q	
H_1H_2	× H_1H_2	p^2q^2	$2p^2q^2$	p^2q^2
H_1H_2	× H_2H_2		pq^3	pq^3
H_2H_2	× H_1H_1		$p^3q^2(1+t)$	
H_2H_2	× H_1H_2		$pq^3(1+t)$	pq^3
H_2H_2	× H_2H_2			q^4
Total		p^2	$2pq(1+\frac{1}{2}sp+\frac{1}{2}tq)$	q^2

Genotype	H_1H_1	H_1H_2	H_2H_2
Selective value	$a = 1$	$b = 1 + \frac{1}{2}sp + \frac{1}{2}tq$	$c = 1$

From Fisher's[8] formula we find that there is a stable equilibrium when:

$$q = \frac{b-a}{2b-a-c} = \frac{\frac{1}{2}sp+\frac{1}{2}tq}{sp+tq} = 0{\cdot}50$$

Differences in survival between the two homozygotes will, of course, alter the point of balance. Our model resembles one given by Hull[9], except that we assume no selective disadvantage of the heterozygous offspring from heterozygous mothers. It also differs from Hull's in giving stability over a wider range of conditions. Hull[9,10] puts forward his model to represent the results of experiments in which he crossed two inbred strains of mice (*C3Hf/He Ha* agouti and *HG/Hu* black-and-tan). He found that litters were deficient in young whose coat colour genotype resembled that of the mother. As he pointed out, this deficiency may not be the result of the action of the coat colour genes themselves, but of the action of loci sufficiently closely linked to remain associated with them through several meiotic divisions. It is significant in this context that the histocompatibility locus *H3* is known to be closely linked with the locus which controls the agouti character[11]. However, an explanation of Hull's results in terms of histocompatibility must account for his finding that there is a deficiency of heterozygous offspring from heterozygous mothers. There are two possibilities: either there is antigenic recognition by the foetus as well as by the mother, or the heterozygous young suffer a disadvantage unrelated to their immunological status—a disadvantage which is overcome when the mother can react against them.

The experiments reviewed in this communication show that immunological interactions between mother and foetus can influence foetal size and probably foetal survival. The effects of transplanting paternal tissues into the mother suggest that histocompatibility antigens are involved in these interactions. The data indicate a selective system capable of maintaining balanced polymorphism, and they provide a possible explanation of the great genetic diversity of transplantation antigens within species of viviparous animals.

Effect of Thymectomy on Transplantation Resistance induced by Polyoma Tumour Homografts

POLYOMA virus will induce neoplasms in most strains of newborn mice but not usually in mice older than 2 weeks[1,2]. Adult mice infected with polyoma virus are relatively more resistant to challenge of syngeneic polyoma-type tumours[3]. Such resistance can also be induced by homografts of polyoma tumours[4]. This resistance is not dependent on circulating viral antibodies and can apparently be transferred to normal recipients by lymphoid cells from immunized mice. To interpret these findings, Habel[5] and Sjögren *et al.*[6] proposed that polyoma virus transforms normal cells to neoplastic cells in the newborn and in the adult mouse, and that the transformed cells now contain a new foreign cell antigen which will provoke an immune response in the adult but not in the newborn animal. Thus, ordinarily, neoplasms will arise in newborn animals, whereas adult animals are capable of rejecting tumour cells containing foreign antigen. This tumour antigen is apparently common for most polyoma tumours induced by the same strain of virus[7]. This concept is supported by the finding that thymectomy during the immediate postnatal period—known to effect maturation of immunological faculty—can alter the course of polyoma virus oncogenesis. Thymectomy at 3 days of age rendered normally highly resistant (*C57BL*) mice susceptible to the oncogenic action of polyoma virus[8]. The same effect was found when the virus was injected into mice 1 month old[9]. Mice thymectomized when 3 days old and then infected with polyoma virus were unable to develop transplantation resistance against a challenge of syngeneic polyoma tumour cells[10]. Additional evidence is now reported that *C57BL* mice, thymectomized at 3 days of age and then immunized with homografts of polyoma tumour cells when 1 month old, are unable to develop resistance against challenge by syngeneic polyoma tumour cells.

Polyoma tumour 4198 originated *in vitro* in tissues derived from a *C3Hf/Hen* strain of mouse[10], and polyoma tumour-89 originated in a *C57BL/KaLw* thymectomized mouse. Both tumours were induced by the LID_1 strain of polyoma virus. They are both transplantable tumours and grow progressively until they kill their syngeneic hosts; they have been cultivated *in vitro* for many generations. Both tumours are free from demonstrable virus as determined by the haemagglutination inhibition test and by plaque formation, but the polyoma tumour specific antigen is known to be present as determined by transplantation resistance tests.

Adult mice (1–2 months old) were given homografts of polyoma tumours (4,198 cells to *C57BL* mice or 89 cells to *C3H* mice) as follows: 2×10^6 trypsinized cells suspended in *tris* buffer were injected subcutaneously. At the first inoculation an initial outgrowth was often seen, followed by regression as the result of a homograft reaction. On complete regression of the first homograft a second inoculation of 2×10^6 cells was made. No temporary growth was observed on this occasion. A third inoculation of 2×10^6 cells was given 2 weeks later. Two to three weeks after this all mice were challenged subcutaneously with syngeneic polyoma tumour cells. The animals were observed for a minimum of 60 days after challenge.

The results in Table 1 show that a homograft of polyoma tumour cells indeed induces transplantation resistance. *C57BL* mice were better recipients than *C3H* mice. This is because *C57BL* mice are immunologically more competent early in life[11]. Similar results have been obtained for transplantation resistance developed against Moloney lymphoma. After they had been immunized by homografts of Moloney lymphoma, *C57BL* mice developed stronger resistance to syngeneic challenge of Moloney lymphoma than other strains of mice such as *BALB/c*

Table 1. R_F AND SPECTRAL PROPERTIES OF PRODUCTS FROM *E. coli*

Experiment No.	Spot designation	R_F	*A* ratio (265/355)
1	*A*	0·68	–
	B	0·78	–
2	*C*	0·66	3·83
	D	0·78	3·31
3	*E*	0 95	–
	F	0 69	–
	G	0·75	–
Standard	OTC	0 76	1·24
Standard	Tetracycline	0·78	1·11
Standard	Desdimethylamino-oxytetracycline	–	1·32

The experiments were run as follows: Cells from 50 ml. of nutrient broth culture incubated for 15 h at 37° C were collected by centrifugation and washed twice with water. They were resuspended in 50 ml. of a salts and glucose medium containing OTC (50 μg/ml.), and incubated for 105 min at 37° C with shaking. The cells were recovered by centrifugation (yield about 100 mg wet weight). The cells were extracted with 10 per cent TCA at 0° C for 1 h. The TCA was removed by three extractions with ether. The extract was freeze dried to concentrate the material, then resuspended in a small volume of water, and analysed by ascending paper chromatography in a solvent of isobutyric acid—0·5 N ammonium hydroxide (5 : 3). Chromatography was extended over 15 h at room temperature (about 25° C).

Except for experiment No. 2, it has not been possible to elute the spots from the paper after chromatography; this has greatly limited the scope of the investigations so far. The results given in Table 1 would seem to demonstrate that three new compounds are formed from OTC during the incubation period. These are, respectively, a material of slower R_F, faster R_F, and the same R_F as OTC. The spectral properties of the R_F 0·78 material suggest that it is not the parent compound. A control exposure of 5 mg/ml. of OTC to 9 per cent TCA for 1 h at 0° C resulted in only one spot on paper chromatography, of R_F 0·78 and an absorbancy ratio (265/355) of about 0·96. It was apparently unchanged OTC. Another control experiment showed that no fluorescent spots were extracted from *E. coli* carried through this procedure when OTC was omitted from the incubation mixture. Immersion of cells in a boiling water bath for 15 min before exposure to OTC completely eliminated their ability to convert the drug to these new compounds. The ability of the *E. coli* to concentrate OTC from the external medium[2] was destroyed concomitantly. Although alternative explanations are possible for these observations, it would appear that bacterial viability is essential for the observed changes in the OTC to occur. These changes are presumably the result of enzyme catalysed reactions within the bacteria.

When bioautographs were prepared from the paper chromatograms (experiment No. 3), using *Staphylococcus aureus* as the test organism, clearly defined zones of inhibition were apparent for all three spots. Thus these compounds retain antibacterial properties.

Note added in proof. After the submission of this manuscript, Izaki and Arima (*J. Bacteriol.*, 89, 1335; 1965) reported further details of the uptake of OTC by *E. coli*.

Specific Activity of Phenylalanine Deaminase in Extracts of the *Proteus–Providence* Group

THE possession of a phenylalanine deaminase which converts phenylalanine to phenylpyruvic acid is one of a combination of five properties unique for the *Proteus–Providence* group of organisms[1]. Of a total of 185 *P. hauseri* (*P. mirabilis* + *P. vulgaris*), 155 *P. morganii*, 29 *P. rettgeri* and 239 *Providence* strains qualitatively examined for the presence of this enzyme[2–4], all but two *Providence* strains[3] were positive, although *P. morganii* strains have been reported to yield on occasions weak or negative results[5].

As part of an investigation of this enzyme, its specific activity in extracts of the *P. hauseri*, *P. morganii* and *P. rettgeri* strains previously used[6] was investigated. An additional fifty-seven strains of *P. morganii* were also examined. The strains were grown overnight on Difco nutrient agar supplemented with 0·3 per cent extracts of yeast. Organisms were collected and placed in 0·8 per cent saline and sonicated at 9 kc/s for 20 min before they were centrifuged in the cold at 198,000*g* for 30 min. Protein concentration in the cell-free supernatant was measured by the biuret method and crystalline bovine albumin was used as the standard. The specific activity of phenylalanine deaminase in the supernatant was measured by incubating 1·0 ml. with 0·2 M *tris*-hydrochloric acid buffer at *p*H 7·4 (1·0 ml.) and 0·08 M D,L-phenylalanine (1·0 ml.) for 60 min at 37° C after which the reaction was stopped by the addition of 40 per cent trichloroacetic acid (1 0 ml.). A blank was included for each sample with the trichloroacetic acid added and mixed before addition of the phenylalanine. After centrifugation, 1·0 mL samples of the supernatant were adjusted to *p*H 2 and assayed with ferric chloride for phenylpyruvate content by the method of Rowsell[7].

Table 1. PHENYLALANINE DEAMINASE ACTIVITY OF *Proteus* AND *Providence* ORGANISMS

	No. strains	< 50	50–2,000	2,000–4,000	4,000–10,000
P. mirabilis	19	—	—	—	19
P. vulgaris	9	—	—	—	9
P. rettgeri	22	4	18	—	—
P. morganii	74	—	5	69	—
Providence	24	—	6	18	—

Overnight nutrient agar growths were collected and placed in 0·8 per cent saline and sonicated in the cold. After centrifugation at 4° C, the phenylalanine deaminase activity of the clear supernatants was determined and expressed as μmoles phenylpyruvate formed/mg of protein/min.

Results are presented in Table 1. Results were not affected by the incorporation of 0·2 per cent D,L-phenylalanine in the growth medium and the striking feature is the high deaminase activity of *P. hauseri* extracts. *P. hauseri* differs from the other groups of organisms investigated here in its pronounced swarming capacity and the ability to ferment xylose, to produce hydrogen sulphide and to liquefy gelatine. The quantitative difference in phenylalanine deaminase activity demonstrated may support claims[1,8] that biochemical differences among these groups of organisms are at generic level within a tribe Proteae.

GENERAL

Origin of the Theory of Errors

J. H. LAMBERT should be given precedence over Gauss as the originator of the theory of errors. Galle[1] stated that Gauss arrived at the idea of the principle of least squares while reading Lambert, but he did not mention the essence of Lambert's work on the subject. Furthermore, no mention has been made of this in the various works on Lambert[2–4]

The three main works by Lambert are *Photometria*[5], *Theorie der Zuverlässigkeit der Beobachtung und Versuche*[6], and *Aumerkungen und Zusätze zur practischen Geometrie*[7]. The first of these is available in the Ostwalds' *Klassiker* series, but the relevant portion was omitted from the translation. Moreover, the translator inserted a special comment on this portion asserting that it contained nothing of interest to readers.

These works contain:

(*a*) The first general outline to be published after Galilei[8] of the properties of observational errors.

(*b*) A rule for estimating the precision of measurements by comparing the means taken with and without the most extreme observation. This was the first numerical rule for such estimations, but was inadequate for a comparative estimation of various series of data which differed in the number of their individual observations.

(*c*) A somewhat loose proof of the preference for an arithmetical mean as compared with individual observations (ref. 7, art. 443–5).

(*d*) A derivation (ref. 7, art. 429–30) of a curve named later by Laplace "a curve of facility of errors", which because there were "no reasons" for supposing the existence of an "angle" (*eckige*) form took the shape of a semicircumference. The same manner of reasoning was used in similar circumstances by Laplace in 1774:

$$d\varphi(x+dx)/d\varphi(x) = \varphi(x+dx)/\varphi(x)$$

as there was "no reason" to suppose that there were different laws for $\varphi(x)$ and $d\varphi(x)$ (ref. 9).

(*e*) A definition of the objectives of the theory of errors. Possibly even the term itself should be credited to Lambert (see foreword in ref. 6), although in this connexion Lambert often mentions Marinoni's *De re ichnographica* (see ref. 6, art. 12). As to the aims, these are (ref. 6, art. 321) to find connexions between errors, the consequences of errors, circumstances of observations and the accuracy of instruments (*Verhältnis zwischen den Fehlern, ihren Folgen, den Umstanden der Ausmessung und Güte des Instruments*). The *Theorie d. Folgen* was classified independently as having as its objective the study of errors of functions of observed elements. But Lambert then introduced (ref. 6, art. 1) reliability (*Zuverlässigkeit*) of observations and implied that the aim of the corresponding theory was to deduce the "true value" and to estimate the accuracy of observations. The classification now seems rather clumsy; however, taken as a whole, a "united" theory of errors emerges.

(*f*) An enunciation of the "minimax" principle (minimization of the maximum residual error in geodetic adjustments—the minimum being sought among all possible solutions (ref. 7, art. 420)). But Lambert confessed that he did not know how to use this principle "in a general manner, without many devious ways" (*auf eine allgemeine Art, und ohne viele Umwege*). The use of this principle in a rudimentary form for solving a redundant system of linear algebraic equations should be credited to Euler[10].

(*g*) Rules for fitting straight lines and curves—the observations being divided into groups and the centres of gravity of these taken instead of original observations (ref. 6, art. 20, and others).

(*h*) The use of the principle of maximum likelihood (ref. 5, art. 299–303). Lambert started from a curve *NMLK* (Fig. 1), the equation of which was unspecified but corresponded with the following properties of observational errors: $\varphi(x)=\varphi(-x)$, $\varphi(|x_2|)<\varphi(|x_1|)$ *if* $|x_2|>|x_1|)>\alpha$. He calculated the number of ways in which the observations P, Q, R and S would occur n, m, l and k times, respectively, as:

$$\frac{(n+m+l+k)!}{n!\,m!\,l!\,k!}PN^n\,QM^m\,RL^l\,SK^k \sim PN^n\,QM^m\,RL^l\,SK^k$$

with NP, MQ, etc., equal to the ordinates of the curve. He then gives a graphical method of maximizing the last product using subtangents. He considered the ordinates to be equal to the corresponding "true number" of observations: in this he was almost copied by Lagrange[11] (problem 10), who held that in a continuous case the "facility of errors" was the ratio of the number of cases of the specified type to the total number of cases.

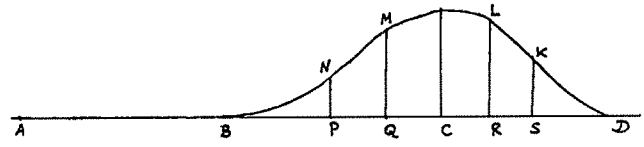

Fig. 1.

Lambert did not specify that his solution was equivalent to differentiating with respect to the unknown mode x_0 of a disintegration $\varphi(x-x_0)$.

It should be noted that Lambert did not regard this principle as a useful one in practice, and he did not return to it.

The χ^2 distribution is due to the German optician, Ernst Abbe[12], and his work is said[13,14] to have been printed in 1863.

Abbe considered the case of normally distributed errors of observations $x_1, \ldots, x_n$ by means of two functions: $\Delta=x_1^2+\ldots+x_n^2$ and $\Theta = (x_1-x_2)^2+\ldots+(x_n-x_1)^2$. Actually he calculated the integral:

$$\frac{h^n}{\pi^{n/2}}\int\ldots\int dx_1\ldots dx_n\, e^{-h^2(x_1^2+\ldots+x_n^2)}$$

(where h is a measure of the precision of the observations), taking (i) $0 < x_1^2+\ldots+x_n^2 < \Delta$; (ii) $0 < (x_1-x_2)^2+\ldots+(x_n-x_1)^2 < \Theta$; (iii) $\Theta < \mu\Delta$, where $0 < \mu <$ by definition of Θ and Δ. He finally arrived at a criterion for rejecting observations with "systematic influences", as they are called in the theory of errors, and noted that departures from the normal distribution correspond to departures of Θ/Δ from 2. But the main point of his work is to be found in (i), where he actually arrived at the χ^2 distribution:

$$P(\Sigma x_i^2\in[\Delta,\Delta+d\Delta]) = \varphi(\Delta) = \left\{h^n/\Gamma(n/2)\right\} e^{-h^2\Delta}\Delta^{\frac{n}{2}-1}\,d\Delta$$

Helmert[15] introduced into geodetic literature what he called a "modified" Abbe's criterion; however, he never mentioned Abbe's deduction of the χ^2 distribution, and this is one of the reasons why the origin of this distribution is usually ascribed to Helmert[16].

FORTHCOMING EVENTS

(Meetings marked with an asterisk are open to the public)

Wednesday, August 31—Wednesday, September 7

BRITISH ASSOCIATION FOR THE ADVANCEMENT OF SCIENCE (at Nottingham)—128th Annual Meeting.

Wednesday, August 31

At 7.30 p.m.—Prof. Sir Joseph Hutchinson, C.M.G., F.R.S.: "Land and Human Populations" (Presidential Address).

Thursday, September 1

At 10 a.m.—Prof. R. S. Nyholm, F.R.S.: "Intermetallic Bonding in Metals and Chemical Compounds" (Presidential Address, Section B).

At 10 a.m.—Prof. J. W. S. Pringle, M.B.E., F.R.S.: "The Treasure-House of Nature" (Presidential Address, Section D).

At 10 a.m.—Prof. G. L. S. Shackle: "Policy, Poetry and Success" (Presidential Address, Section F).

At 10 a.m.—Prof. J. Greig. "Technique" (Presidential Address, Section G).

At 10 a.m.—Prof. J. D. Matthews: "Forestry and the Landscape" (Chairman's Address, Section K*).

At 10 a.m.—Mr. J. Scupham, O.B.E.: "The Social Factor in Education" (Presidential Address, Section L).

At 10 a.m.—Prof. W. Ellison: "Agriculture and Changes in Land Use" (Presidential Address, Section M).

At 2.30 p.m.—Mr. H. G. Conway, C.B.E.: "The Concord: An International Project in Supersonic Transport" (Young People's Lecture).

Friday, September 2

At 10 a.m.—Prof. W. H. McCrea, F.R.S.: "Cosmical Physics" (Presidential Address, Section A).

At 10 a.m.—Prof. L. R. Moore: "Frontiers in Geology—Geo-Microbiology" (Presidential Address, Section C).

At 10 a.m.—Prof. R. W. Steel. "Geography and the Developing World" (Presidential Address, Section E).

At 10 a.m.—Prof. A. Neuberger, C.B.E., F.R.S.: "The Operation of Control Mechanisms at the Cellular Level" (Presidential Address, Section I).

At 10 a.m.—Sir James Cook, F.R.S.: "The Science Information Problem" (Presidential Address, Section X).

At 11.30 a.m.—Dr. N. A. B. Wilson: "Psychology and Military Proficiency" (Presidential Address, Section J).

At 11.30 a.m.—Prof. A. R. Clapham, F.R.S.: "Nature Conservation and Botanical Research" (Presidential Address, Section K).

At 2.30 p.m.—Prof. F. G. Bailey: "The Peasant View of the Bad Life" (Presidential Address, Section N).

At 2.30 p.m.—Mr. R. L. Gregory: "Illusions in Space" (Young People's Lecture).

At 8 p.m.—Dr. A. H. Cottrell, F.R.S.. "Science and Economic Growth in the United Kingdom" (Evening Discourse).

Sunday, September 4

At 10.45 a.m.—Official Service in St. Mary's Church. Preacher: Canon D. R. Feaver.

Monday, September 5

At 10 a.m.—Prof. J. S. Weiner: "Aspects of Human Adaptation" (Presidential Address, Section H).

At 10 a.m.—Prof. J. N. Bradley: "Shock Waves in Chemistry and Physics" (Kelvin Lecture).

At 10 a.m.—Dr. D. Noble: "How the Heart Beats" (Darwin Lecture).

At 2.30 p.m.—Prof. R.L. F. Boyd: "The Rocket Age" (Young People's Lecture).

At 8 p.m.—Dr. N. Tinbergen, F.R.S.: "Behaviour as Equipment for Survival" (Evening Discourse).

Tuesday, September 6

At 11.30 a.m.—Prof. R. J. Ball: "Economic Model Building for Control" (Lister Lecture).

At 2.30 p.m.—Prof. A. R. Gemmell: "Biology and Crime" (Young People's Lecture).

Monday, September 5—Friday, September 9

BRITISH PHARMACEUTICAL CONFERENCE (at Manchester)—103rd Annual Meeting.

APPOINTMENTS VACANT

APPLICATIONS are invited for the following appointments on or before the dates mentioned:

LECTURER or ASSISTANT LECTURER (with some interest in physical or dynamical oceanography) IN THE DEPARTMENT OF OCEANOGRAPHY—The Deputy Secretary, The University, Southampton (August 31).

TEMPORARY LECTURERS or TEMPORARY ASSISTANT LECTURERS (2) IN THE DEPARTMENT OF PSYCHOLOGY—The Registrar, University Senate House, Bristol, 2 (September 1).

VICE-PRINCIPAL (with proven administrative ability, high academic and/or professional qualifications, and responsible experience in education and/or industry, commerce) OF THE COLLEGE OF TECHNOLOGY, Southend-on-Sea—Chief Education Officer, Civic Centre, Victoria Avenue, Southend-on-Sea (September 1).

RESEARCH ASSISTANT (chemistry graduate) for a biological and chemical survey of the River Wear—The Registrar and Secretary, University of Durham, Old Shire Hall, Durham (September 3).

SENIOR RESEARCH FELLOW (with a veterinary qualification and preferably postgraduate experience in virology or microbiology) IN THE SECTION OF POULTRY DISEASE, DEPARTMENT OF VETERINARY PREVENTIVE MEDICINE, to join a team undertaking research into respiratory diseases of poultry in a new building to be available later this year at the Veterinary Field Station in Wirral, Cheshire—The Registrar, The University, Liverpool, 3, quoting Ref. CV/198 (September 3).

TUTOR IN MEDICINE to give instruction in clinical medicine and to take part in the clinical and research activities of the Department of Medicine—The Registrar, The University, Manchester, 13, quoting Ref. 188/66 (September 3).

LECTURER or ASSISTANT LECTURER in SOCIOLOGY—The Secretary, The University, Aberdeen (September 4).

RESEARCH ASSISTANT (with a degree in geography or agricultural economics or similar qualifications, and preferably a knowledge of agricultural statistics and of statistical mapping) IN THE DEPARTMENT OF GEOGRAPHY to assist Prof. J. T. Coppock in the preparation of an agricultural atlas of Scotland—The Secretary, University of Edinburgh, Old College, South Bridge, Edinburgh (September 5).

RESEARCH ASSISTANT (mycologist or plant pathologist) IN PLANT PATHOLOGY IN THE DEPARTMENT OF BOTANY to join a group investigating obligately parasitic fungi—The Secretary of the University Court, The University, Glasgow (September 9).

CHAIR OF CHEMISTRY—The Assistant Registrar, University College of Cape Coast, 15 Gordon Square, London, W.C.1; or The Registrar, University College of Cape Coast, University Post Office, Cape Coast, Ghana (September 10).

RESEARCH ASSISTANT (veterinary graduate) IN THE DEPARTMENT OF VETERINARY PREVENTIVE MEDICINE at the Veterinary Field Station, Wirral, Cheshire—The Registrar, The University, Liverpool, quoting Ref. CV/204 (September 10).

TUTORIAL RESEARCH STUDENT (man or woman) IN PHYSICS (experimental or theoretical)—The Secretary, Royal Holloway College (University of London), Englefield Green, Surrey (September 10).

LECTURER or ASSISTANT LECTURER (mathematician with research interests in any branch of pure mathematics or mathematical statistics) IN THE DEPARTMENT OF PURE MATHEMATICS—The Registrar, University College of Swansea, Singleton Park, Swansea, South Wales (September 17).

LECTURER (preferably with a special interest in stress analysis) IN THE POSTGRADUATE DEPARTMENT OF APPLIED MECHANICS—The Registrar, The University, Sheffield (September 17).

EXPERIMENTAL OFFICER (with H.N.C. or a university ordinary degree in science, and specially experienced and interested in histological techniques) IN THE DEPARTMENT OF MICROBIOLOGY, for duties which will consist of assisting with and developing methods of studying tissue infected with bacteria, fungi and viruses using techniques for conventional, immunofluorescence and electron microscopy—The Professor of Microbiology, The Queen's University of Belfast, Belfast, Northern Ireland (September 15).

RESEARCH SCIENTIST (statistician) (with a Ph.D. degree in arts or science with mathematics and mathematical statistics as major subjects, or postgraduate research experience or equivalent standard and duration, supported by satisfactory evidence of research ability) IN THE DIVISION OF MATHEMATICS, C.S.I.R.O., to take part in the respective Divisional research programmes of the Division of Protein Chemistry and the Division of Animal Health (Animal Health Research Laboratory) which are closely located in MELBOURNE—The Chief Scientific Liaison Officer, Australian Scientific Liaison Office, Africa House, Kingsway, London, W.C.2, quoting Appointment No. 440/191 (September 23).

SCIENTIFIC OFFICER/SENIOR SCIENTIFIC OFFICER (with a good honours degree in botany or biology and preferably postgraduate experience in ecological research) to take part in the ecological studies of the Nature Conservancy's Conservation Research Division at its Monks Wood Experimental Station, Abbots Ripton, Huntingdon—The Natural Environment Research Council (E), State House, High Holborn, London, W.C.1 (September 24).

LECTURERS/SENIOR LECTURERS (2) IN BIOLOGY (in the field of genetics); and a LECTURER IN BIOLOGY (in the field of whole plant physiology) in the School of Biological Sciences, University of Sydney, Australia—The Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (Australia and London, September 26).

READER IN OBSTETRICS AND GYNAECOLOGY at Charing Cross Hospital Medical School—The Academic Registrar, University of London, Senate House, London, W.C.1 (September 19).

CHAIR OF PHILOSOPHY at the University of New England, Armidale, New South Wales, Australia—The Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (Australia and London, September 30).

JUNIOR DEMONSTRATOR (non medical, preferably with experience in some branch of endocrinology) IN THE DEPARTMENT OF PHYSIOLOGY—Prof. A. A. Harper, The Department of Physiology, The Medical School, University of Newcastle upon Tyne, Newcastle upon Tyne, 1 (September 30).

READER, SENIOR LECTURER or LECTURER IN MICROBIOLOGY at Monash University, Melbourne, Australia—The Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (Australia, September 30).

RESEARCH FELLOW (organic chemist, with a Ph.D. or equivalent research experience) IN THE DEPARTMENT OF MEDICAL CHEMISTRY, The John Curtin School of Medical Research, Institute of Advanced Studies, Australian National University, to work on the synthesis and reactions of nitrogen heterocycles—The Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (Australia and London, September 30).

LECTURER (preferably with experience in the application of physical chemistry to metallurgical problems) IN METALLURGY—The Registrar, The University, Sheffield (October 1).

READER IN GEOGRAPHY at King's College—The Academic Registrar, University of London, Senate House, London, W.C.1 (October 3).

LECTURER (specialist in one or more branches of human geography) IN GEOGRAPHY at the University of Tasmania, Australia—The Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (Australia and London, October 14).

CHAIR OF BIOCHEMISTRY at the University of Melbourne Australia—The Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (Australia and London, October 31).

ASSISTANT EXPERIMENTAL OFFICER/EXPERIMENTAL OFFICER (if aged under 22, five passes in the G.C.E. examination including English at "A" level; if aged over 22, H.N.C. or a scientific degree, preferably in biochemistry or microbiology) AT THE FOOD RESEARCH INSTITUTE, NORWICH, for work on

the biochemistry and physiology of micro-organisms—The Secretary, Low Temperature Research Station, A.R.C., Downing Street, Cambridge, quoting Ref. 66/14.

GRADUATE RESEARCH ASSISTANT (preferably with a knowledge of statistics) to participate in a survey of the careers and previous academic discipline and performance, of engineering and science graduates of Imperial College—The Registrar, Imperial College of Science and Technology, London, S.W.7.

HISTOLOGIST (with an honours degree in physiology or zoology or an equivalent qualification and preferably previous experience in histological techniques) IN THE PHYSIOLOGY DEPARTMENT, to be in charge of the histological work of the Department and to collaborate in research, mainly in the field of endocrinology—The Secretary, National Institute for Research in Dairying, Shinfield, Reading, Berkshire, quoting Ref. 66/N/21.

SENIOR/CHIEF (Physics) TECHNICIAN (female) IN THE PHYSICS DEPARTMENT for duties which mainly involve the use of radioactive isotopes in clinical diagnosis—The Secretary, Dudley Road Hospital, Birmingham, 18.

SENIOR LECTURER (preferably with special interests in physiology and research) IN ZOOLOGY/PHYSIOLOGY—The Principal, Barking Regional College of Technology, Longbridge Road, Dagenham, Essex.

SENIOR TECHNICIAN I (with experience in chemical pathology) to work in the new Renal Transplant Unit in conjunction with the Medical Unit—The House Governor, St. Mary's Hospital, Paddington, London, W.2.

SUB-LIBRARIAN (honours graduate with a librarianship qualification, and preferably experienced in the field of science and technology) IN THE ANDERSONIAN LIBRARY—The Registrar, University of Strathclyde, George Street, Glasgow, C.1, quoting Ref. 52/66.

FORTY MILLION ENGLISHMEN?

SIR JOSEPH HUTCHINSON will have helped enormously to awaken interest in the problem of how people are to continue living in crowded countries. It is tempting, and easy, for the members of industrialized societies to persuade themselves that imbalance between the land and the population it must support is an affliction of remote parts of Asia and Africa. In his presidential address to the British Association (see page 1053, this issue), Sir Joseph has made it plain that advanced societies such as the United Kingdom are as much in peril. Moreover, he has shown that the task of bringing land and population into harmony is not simply one of matching two large numbers comfortably together, but that it is also necessary for the nature of a nation's agricultural system to be harmoniously in character with the structure of its society. It is true that agriculturalists are diligent in pointing out what risks imbalance may entail, but that is no reason to disregard what Sir Joseph Hutchinson had to say on Wednesday. But what of his attempt to say where the balance between the population and the land should be established in the particular circumstances of Britain? Is the ideal population one of 40 million people, or should it be more, or even less? To say that there should be a balance is one thing. To say precisely where it should be struck is quite another. In particular, it is not a task which agriculturalists by themselves can usefully attempt.

To be fair, Sir Joseph Hutchinson did not invest his figure of forty million with moral rectitude, but, rather, he described it as a "target figure". He arrived at it by general arguments, not arithmetic. He was concerned about pollution of the environment and the water supplies, the increasing competition for somewhere to spend a holiday, the encroachments of the conurbations on the countryside, and the supposed "stress and disorientation" of young people forced to live in cities. It is true that if only the population were smaller, some (though not all) of these problems would disappear. But is that all there is to say? Are these problems so serious that the British population should deliberately seek to shrink in numbers? And are there no benefits to be set off against the evident inconveniences of a densely packed population? Is modern life such a gloomy business?

The admitted nuisances of modern life are, of course, a challenge for societies that wish to go on being known as civilized, but the problems of pollution and waste disposal could be tackled with at least as much success as the Victorian banishment of cholera from London. Shortages of water and other natural resources are often exaggerated, as the committee of the U.S. National Academy of Sciences makes plain (see page 1008, this issue). The scarcity of beaches is a function of the cost of air travel, and it is always possible that twentieth century fashion which sends people rushing to the beaches will be replaced by one that is socially more convenient. (In any case, it would always of course be possible to manufacture extra beaches if the need for them were great enough.) In other words, these nuisances and the scarcities are not absolute but relative. One way of dealing with them is for the population of Britain, and of similar countries, to contract; another is to tackle them directly, and to get rid of them.

City life is a ready scapegoat, and nobody will fail to shrink from the kind of encroachment on the countryside, and the ugliness which accompanies it, which is all too plain on the outskirts of most large cities. Yet this, too, is a relative, not an absolute, problem. There is nothing but indifference to decree that a modern city must be an offence against the countryside. Indeed, there is no reason why modern cities should take up so much space. As things are, the largest cities tend to be hollow at the centre, with the result that the social benefits which could flow from the interaction of large groups of people are somehow dissipated in the diurnal flow of the population in and out of the suburbs. It could well be that many of the social problems dangerously apparent in cities such as New York are consequences not of the large size of their populations but of the lack of care with which the populations have been bundled together.

But who is to see that reason is applied? And how? These are the questions that urgently need asking. The answer is not to create more social scientists, whatever that term may imply, for the problems are at once bigger and simpler. What needs to be accepted is that the development of modern technology has created a range of new opportunities, not an array of strait-jackets. In particular, if society wants clean rivers, it can elect to have them. Clean air is also to be had, if at a price. If the countryside is being ruined, that is because the people who use it—farmers included—have not collectively decided that the countryside is worth keeping. Cities would not be choked with traffic if those who live and work in them were really anxious to have a more rational system of transport. And the great cities of the world could be allowed to become even more populous (though not necessarily bigger on the map) and at the same time still more rewarding to live in if the social complexities of city life were properly acknowledged and dealt with.

Agriculture is important but not central. Sheer starvation is not the only consequence of the rapid increase of the population of the world, and may not even be the most serious. For every stomach that needs to be filled with food, there is a head that must be given some sense that the future will be better than the present. It is not easy to persuade such populations that they must recapitulate the evolutionary steps which more advanced societies have left behind them. In other words, the advice that they should first create a manual agricultural system on the pattern of English agriculture in the eighteenth century, wise though it may be, is likely to smack of what is called neo-colonialism. For this reason if for no other, it is com-

forting that the steady rise of agricultural productivity in the temperate zone of the Northern Hemisphere shows no sign of coming to a halt. For at least some time to come, the war against famine will have to be fought on the prairies of North America. In the long run, countries now undeveloped may practise novel forms of agriculture—or even buy wheat by exporting manufactured goods. At this stage there is no knowing just what will happen, but disaster and a repetition of familiar patterns are not the only possibilities.

MEDICAL RESEARCH

THE Medical Research Council is one of the most successful of the research councils responsible for the support of research in Britain, and the annual report for 1965–66 now published (see page 1009, this issue) is another cheerful story. Good works continue. New projects are being started, and promise to fill glaring gaps in the pattern of what is being done. The clinical research centre now being built will obviously do well, for example, even if it is not entirely clear why it should not have been created by the development of a teaching hospital.

Why does the Medical Research Council persist in getting such good value for its money ? Much probably depends on the way in which the council organizes its grant giving. More than half the annual budget last year was spent on supporting what are called the research units—groups of people ranging in size from a handful to a hundred—who are employed full-time by the council, kept supplied from the same source with equipment, yet free to play a full part in the intellectual life of the university or hospital in which they are sited. Although units like these are not unknown in other fields, the Medical Research Council has made by far the fullest use of them. A part of the reason for this, no doubt, is that it is often easier to specify a field of study than a particular objective, but the council has also been shamelessly but successfully living by the principle that it is better to back a man than a problem. Obviously there is a model here for other research councils to study if not to copy.

That said, however, it should be recognized that there may be snags. One is that the council may not be able to spend as much as it should on the support of research by young graduates, medically qualified and otherwise. Another is that the first charge on the council's budget is bound to be the salary bill of its full-time staff, not to mention their pension rights and other needs. An awkward consequence is that the budget must be less flexible than its total size would indicate. There is possibly a case for saying that the council would be happier with more elbow room within the framework of its budget. And there is certainly a case for asking that in future annual reports the council should substitute for the scant half-dozen pages now devoted to administrative matters a thorough discussion of the evolution of ways in its policies on these and other matters.

NEWS AND VIEWS

Fresh Thoughts on Water

PRESIDENT KENNEDY said that whoever solved the problems of water deserved two Nobel prizes—one for science, one for peace. The committee of the National Academy of Sciences which has just taken a cold look at water resources in the United States will certainly not get the latter for its frank analysis of what is wrong with American policies for managing water. The trouble is, in brief, the "quick fix" approach. Enthusiasts spring up, hot to build desaturation plants, hydroelectric dams near the Grand Canyon or—the champion here is President Johnson himself—clean whole rivers such as the Potomac from top to toe. Each of these plans, the N.A.S. report says flatly, is short-sighted. What is needed is intelligence and an end to rigid, departmental thinking.

There is no question that it is possible to make drinking water by removing the salt from sea water. But it is expensive and, once elaborate installations are set up for the purpose, little thought is given to alternatives which may be cheaper. The President's plan to purify the Potomac is fine—but prepared without sufficient attention to the changes that its proposals would bring to the soil, plant and animal and even human life along the sweep of the river. And, while conservationists see no lack of arguments for opposing the proposed dams on the Colorado River, the N.A.S. report makes a point that will hurt the advocates of water power; not enough thought has been given to the possibility that hydroelectricity will lose its value in the years to come.

In general, the committee found that the United States would have enough water to drink for the rest of the century, even though regional scarcities will persist. But there are big gaps in research into water resources, and the committee hopes that these will be filled. More should be known about the ways in which the environment—particularly when it is overlaid with tarmac—affects water. New techniques should be developed for treating waste water and, above all, people should start thinking about how to tap the underground supplies which constitute 97 per cent of the world's usable water.

Nothing the N.A.S. report said will dampen spirits in California, where mutual congratulations are being exchanged over the completion of a complicated agreement between the federal government, local authorities in Los Angeles and private electricity companies to build the world's largest desalination plant. A quick fix could not be applied in a better spot than parched populous southern California, in a constant wrangle with neighbouring states to use their water. (It now has eyes on the Columbia River far to the north-west.) The Los Angeles station, to be built on a man-made island offshore, will use nuclear power and do double duty, generating 1·8 million kWh of electricity a day while refining 150 million gallons of sea water as well, and at a cost which, if estimates are borne out in practice, will be as little as 23 cents a thousand gallons. The plant will cost $438 million, of which the federal share will be $72 million, and should go into action in 1971.

More Medical Research

THE budget of the Medical Research Council for 1965–66 was comfortably greater than that in the preceding year. According to the annual report now published, £11 million were spent in 1965–66 compared with £9·6 million in 1964–65, an increase of roughly 15 per cent. More than 90 per cent of the council's income consists of a parliamentary grant and another £770,000 is provided by government departments and public bodies in return for services rendered. The council spends most of its income on the current expenses of research units and laboratories throughout the United Kingdom and a comparatively small amount—£373,000 in 1965–66—on new buildings. The National Institute for Medical Research at Mill Hill, London, accounts for one-eighth of the total budget, roughly a half of which, or more than £5 million, is spent on research units and external scientific staff.

The council is clearly pleased with developments at the Clinical Research Centre at Northwick Park in North London. The annual report recalls that in the late fifties the council decided there was a need for a clinical research centre in Britain bringing together "clinical and para-clinical workers". The Northwick Park centre is being built in collaboration with the North West Metropolitan Regional Hospital Board. It will consist of a research institute, a laboratory, lecture hall, and accommodation for patients. The research institute itself will be a substantial building with 100,000 sq. ft. of space, and there will also be supporting facilities—an animal house, workshops, and so on. One wing of the hospital ward block, containing 140 beds, has been specially designed to meet the needs of research workers, principally by incorporating research laboratories into the main structure of the hospital. The annual report for 1965–66 records that Professor G. M. Bull of Queen's University, Belfast, has been appointed director-designate of the centre and that Dr. Richard Doll, of the M.R.C. Statistical Research Unit, has been appointed deputy director. Professor Bull is principally interested in renal and tropical diseases and the study of the balance of electrolytes within the body. Dr. Doll has won a considerable reputation by his statistical analysis of the aetiology of various kinds of cancer and of peptic ulcers.

As in previous years, the annual report also includes a review of the work of the various laboratories and research centres which the council supports. There is also a record of the council's involvement with public affairs, and in particular a reminder that it was primarily responsible for providing the Home Office with the information and advice on which it was actually decided to introduce legislation about the permissible content of alcohol in the blood of car drivers.

According to the report, the total staff of the Medical Research Council was 3,410 at the beginning of 1966. There were 809 scientific staff and 1,402 technical staff, and the total includes the personnel of the 79 research units (four of them abroad) which were in being at the end of the financial year. In the course of 1965–66 one unit (for obstetric medicine at Aberdeen) was closed on the retirement of the director, and three were established at Newcastle (the Reproduction and Growth Research Unit), Aberdeen (the Medical Sociology Research Unit) and at Hammersmith (the Cardiovascular Research Unit). During the same year the council undertook to support ten new research groups, bringing the total to 40. A research group differs from a unit, in the council's terminology, in that its staff is employed by the university or hospital concerned, which also agrees to relieve the council of financial responsibility within five years.

Porter of the R.I.

PROFESSOR GEORGE PORTER formally took up his post as Director of the Royal Institution on September 1, and his chemical research group is expected to take up quarters in the Davy–Faraday Laboratory within a week or so. Preparations for the arrival of Professor Porter and his team have been under way for some time, and substantial alterations have been made to the laboratories and the domestic rooms at the building in Albemarle Street. The members of the institution plan to welcome Professor Porter and to say goodbye to the retiring director, Sir Lawrence Bragg, when the latter returns from the United States in the autumn.

The immediate effect of the change of directors will be a shift in the emphasis of the research programme at the laboratory away from X-ray crystallography, which has been dominant there for several decades. Since the War the Royal Institution has housed the work of Professer J. D. Bernal on the structure of silicates, that of Dame Kathleen Lonsdale on the structure of ice and diamonds and, recently, that of Professor D. C. Phillips on lysozyme. This tradition of X-ray crystallography has, of course, been fostered in the past seven years by the distinction of Sir Lawrence Bragg in that field. Professor Porter has been concerned with flash photolysis at the University of Sheffield, though his career has been varied. In the mid-fifties he spent some years as deputy director of the British Rayon Research Association in between academic appointments at Cambridge and Sheffield.

The question of how the change of directors will affect the outward activity of the Royal Institution is probably more absorbing and more important, though at this stage there is only guesswork to go on. Sir Lawrence Bragg has sought to carry out the task of conveying science to the public by building up a series of lectures on science for schoolchildren—without, of course, diminishing the importance attached by the members of the Royal Institution to the ceremonial lectures on Friday evenings in season. It would be in character if Professor Porter aimed at an older age group. The fact that he does well on television may be a clue to what will happen, although Sir Lawrence Bragg has been no mean performer. But these are only details. The central question is the one that has faced directors at the Royal Institution for the past thirty years—how to make full use of the plant, and make a real bite on public awareness of science, without seriously disturbing the traditions of the place, jealously guarded as they are

Research in Japan

JAPAN maintains itself as a major industrial power even though research expenditure there falls short of that of any other highly industrialized nation. Expenditure in 1964 was £438 million, representing

1·9 per cent of the national income, compared with spending in Britain in the same year of £750 million (2·9 per cent). Of the total more than a quarter was spent by the vigorous chemical and chemical engineering industries. A survey in 1962–63 by the Japanese Ministry of International Trade and Industry showed that, in one sense, Japan is running at a deficit, spending more in royalties on foreign patents than she earns on her own patents; in 1964 the royalties paid on foreign patents amounted to nearly £50 million. Japan's defence estimates for 1966 are paltry in comparison with those of comparable countries (£336 million against nearly £2,500 million for the United Kingdom), but savings in defence do not seem to have released money for research. How has Japan managed to run a successful economy without the expenditure on science and technology which is nowadays regarded as a prerequisite ?

The answer may be that Japan squeezes the maximum value out of each yen spent on research. An example of this is her admittedly unsophisticated space research programme, in which eight satellites are to be launched for a total cost of less than £22 million, spread over a long period of time. Somehow Japanese scientists have managed to carry out the programme at an annual expenditure of less than £3 million, and without the escalation of costs that has bedevilled British projects and joint European endeavours such as ELDO. In 1964 the outlay for each research worker in Japanese research was £2,250, the total budget of £438 million being divided among 195,000 research workers. This is a remarkably low figure, to be compared with a figure of about £10,000 per annum in the United Kingdom. While the figures may not be strictly comparable—it is not quite clear what definition of a qualified research worker is applied in Japan—they do indicate a wide disparity. It would seem that Japan maintains industrial momentum by an understanding of cost-effectiveness in research. There is no doubt, too, that in the short term the speed at which scientific research can be translated from the laboratory bench to the factory floor is more important than the volume of work in progress. There is, for example, a flourishing Japanese electronics industry.

New Zealand Science

EXPENDITURE on science in New Zealand is increasing steadily, both absolutely and as a percentage of the Gross National Product. This is plain from the report of the National Research Advisory Council for the year ended March 31, 1966. The report says that expenditure has increased by a factor of 3·2 since the year ending in 1955, although the increase in prices since then implies a real increase in expenditure by a factor of 2·3. During this period the number of scientific staff employed in government departments has increased by only 55 per cent. Table 1 shows the actual expenditure on science in New Zealand in alternate years in the past decade (excluding sums of money spent on buildings). The table also shows the way in which the number of scientists employed in government departments has increased.

Table 1

	Actual expenditure £(000)	As percentage of G.N.P.	Scientific staff in government departments March 31	Expenditure at 1966 prices
1955	2,733	0·27	568	100
1957	3,547	0·35	592	123
1959	4,110	0·36	628	133
1961	4,912	0 38	684	153
1963	5,759	0 40	754	172
1965	7,428	0·42	819	209
1966	8,709*	0·46*	882*	233*

* Estimated.

Of the total expenditure on science in the current financial year, the council estimates that 74 per cent will be spent by government departments, of which the Department of Scientific and Industrial Research takes slightly more than half. Universities spend £800,000, or between 8 and 9 per cent of the total in New Zealand on research.

As a result of a detailed review of research policy carried out in previous years, the council has recommended to the Government of New Zealand a considerable increase in the scale of building research, which is estimated to cost £330,000 in the current year and which will be increased by some 18 per cent in the course of the following three years. Advice for industry and research in transport are also to be increased, and an attempt is to be made to bring the meteorological service up to strength. Work at the Institute of Nuclear Sciences (of the Department of Industrial and Scientific Research) will be extended, principally by the purchase of a 20,000-c. cobalt source.

Foot in the Door

THE Committee of Vice-Chancellors and Principals of England and Wales is delighted with a modest step towards rationalizing entrance requirements to universities now agreed upon by 29 out of 35 universities. The universities concerned have agreed to adopt one or other of two patterns of examination qualifications as a condition for university entrance. One pattern includes five passes in General Certificate of Education examinations, with at least two passes at the Advanced level; the other, intended to cater for students at technical colleges and other such institutions, involves four passes in GCE examinations, three of them at the Advanced level. Particular universities will continue to accept students with various other patterns of qualifications in GCE examinations but, apparently, the number of different patterns acceptable to the universities of England and Wales has been reduced from 19 a year ago to 9 this year.

The universities which have chosen to stand aloof are not all black sheep. In fact, the University of Lancaster requires less of intending university students than either of the two patterns now uniformly adopted. The Universities of Warwick, Keele and Exeter differ from the general pattern in requiring either a language or English qualification from those wishing to become scientists. The universities of Oxford and Cambridge, predictably, have not yet modified their matriculation requirements sufficiently to conform with the general pattern, although there is optimistic talk that Cambridge is considering relaxing the requirements of two language qualifications for intending scientists.

None of this, of course, diminishes the strongest pressure of the universities on the schools—the way in which particular departments or faculties in British universities require particular subjects to have been studied at school by intending students. It remains possible for a student to satisfy entrance requirements

without being able to persuade a university department to teach him what he wants to learn. (The continuing complexity of course requirements is in the edition for 1967–68 of *A Compendium of University Entrance Requirements for First Degree Courses in the United Kingdom*, Association of Commonwealth Universities, 14*s*. 6*d*.) But the Committee of Vice-Chancellors has embarked on a study of that problem too, even though a commonly agreed solution cannot be reached for two years or more. Five sub-committees of the vice-chancellors' committee are studying the course requirements of universities in the physical sciences and mathematics, biological sciences, medicine, humanities and the social sciences. Those serving on these committees are said to be surprised at the way in which universities are prepared to relax previously stringent requirements, but it remains to be seen whether this tendency will be sufficient to allow the schools, in their turn, to liberalize curricula.

Too Much Room at the Top

THE general impression in British universities that the shortage of laboratory technicians is most acute at the top of the salary scale has been confirmed by a study carried out by the Edinburgh branch of the Association of University Teachers. While most of the research workers in the various departments of the university were dissatisfied with the number of technicians available, a "considerable body" was convinced that the number of junior technicians was too high compared with that of more senior people. Among the reasons for this imbalance is the lack of a suitable career structure for university laboratory technicians. In particular, salary scales are too low and, the authors of the study infer, "the university is at present becoming a training ground for technicians which is increasingly valued by outside employers". This conclusion, based on a systematic survey of seventeen departments at the university, is borne out by the impressions of universities elsewhere.

One of the recommendations which arise from the survey at Edinburgh is that there should be a general improvement of salary scales and that in particular the Whitley Council scale should be adopted by all and not merely by some departments. Another suggestion is that the more senior people should in future salary reviews be more generously treated than those at the bottom of the ladder. It is also suggested that promotion to senior technician should not be determined by vacancies at this level, but that this grade should be recognized as one to which qualified and capable technicians would in due course automatically graduate.

The authors of the survey also have a number of suggestions to make about the training of technicians. In the first place it was thought that more could be done by the teaching staff of departments to help with the training of technical staff. Apparently, at Edinburgh day release for junior technicians is habitual and many departments even allow day release to technicians who are older than 21. In the long run it is thought that much could be done to bring more technicians into research work, especially during vacations, and also that those public bodies which award research grants should take fuller account of the need of technical assistance and the need that technical assistants should have some promise of a secure job, possibly beyond the duration of the research grant concerned.

These findings and suggestions will no doubt be widely echoed in other British universities. More is likely to be heard of this issue in the autumn, when the Committee on Scientific Manpower under Sir Willis Jackson is due to report on this and other matters.

Use More Wood

THE Forest Products Research Laboratory of the Ministry of Technology has been devoting more of its time and resources to the considerable problems of wastage in the use of timber. In the introduction to the annual report for 1965, Mr. B. K. Blount, chairman of the laboratory's Steering Committee, says that timber and timber products represent 10 per cent, or £500 million, of all imports into the United Kingdom in a year, and that imports of sawn timber and plywood alone account for more than £200 million. While the supply of home grown timber is increasing, so is the demand; and it is likely that Britain will continue to depend on imported timber for most of its supply. The report says, however, that "economies could be achieved by improvements in processing methods, by the wider application of correct methods of timber usage and by the utilization of low-quality wood which is at present neglected or discarded".

The laboratory plans to work in close collaboration with the public authority recently set up by the Ministry of Public Buildings and Works to evaluate new building components and materials; test work on timber materials will be carried out at the Forest Products Laboratory where it is thought that the interest of the authority will complement its own increasing appreciation of the structural value of wood in building. New methods of construction with timber provide the substance of several investigations being undertaken for industry.

Computing Centre

THE National Computing Centre is slowly building up steam, and has just ordered its first computer, an English Electric Leo Marconi *KDF*9, which should be installed by next April. In the meantime, recruiting is under way and work has begun on the site at Manchester.

The present cost of the centre, which was established as a public company in June, is being borne by the Ministry of Technology, but the Ministry's grant of £290,000 for the first year of operation will not go far when the *KDF*9 alone costs £400,000. Professor Gordon Black, the director of the centre, hopes that it will be independent of the government within a few years, through dues from member organizations and payment for services.

One of the centre's first acts has been to support a one-year course for systems analysts being started this October at Imperial College, London. Professor Black considers that this course, which will combine computer techniques with optional subjects ranging from accountancy to operational research, fulfils a major need. There is a possibility of another course being offered at the London School of Economics early in 1967. Professor Black also sees the centre as advising industry at large on the use of computers. He hopes

to be able to set up a catalogue of computer programmes to include all the programmes available. Professor Black is not interested in doing specific jobs for industry but rather in "getting the industry off the ground". With this in mind he hopes to provide software for hospitals, for the gas and electricity boards, and for industry at large in cases where a number of firms are working on the same problem. He also believes that a major task of the centre will be to work towards a standardization of computer languages—there are 12 in use in Britain at present which he hopes to reduce to two by the time the regional computing centres are established.

University News:

London

DR. BRIAN DONOVAN has been appointed professor of physics at Westfield College. Prof. R. W. Tiffen has been appointed to the chair of mathematics, tenable at Birkbeck College. The title of professor has been conferred on the following members of the teaching staff of Chelsea College of Science and Technology, which was admitted as a School of the University of London as from August 1: Dr. A. H. Beckett (pharmaceutical chemistry); Dr. G. M. Bell (applied mathematics); Dr. S. E. Dicker (physiology); Dr. J. F. Dippy (chemistry); Dr. A. K. Jonscher (solid state electronics); Dr. K. W. Keohane (physics); Dr. A. G. Morton (botany); Dr. R. D. Purchon (zoology); Dr. H. J. V. Tyrrell (physical and inorganic chemistry). The title of professor has been conferred on the following: Dr. L. S. Bosanquet (mathematics, in respect of his post at University College); Dr. S. P. Datta (medical biochemistry, in respect of his post at University College); Dr. F. F. Heymann (physics, in respect of his post at University College); Dr. R. M. H. McMinn (anatomy, in respect of his post at King's College); Dr. J. L. Mongar (pharmacology, in respect of his post at University College).

Announcements

THE Enrico Fermi Award of the United States Atomic Energy Commission has been awarded for the first time to scientists outside the United States. The Atomic Energy Commission announced last month that Professor Otto Hahn, Professor Lise Meitner, and Professor Fritz Strassmann, of Germany, have each been awarded a third share in the $50,000 prize together with the customary gold medal. Professor Meitner, who worked with Hahn and Strassmann at the Kaiser Wilhelm Institute on the fission of uranium, now lives in Cambridge, England.

Two new journals, *Chemistry and Physics of Lipids* and *Cell Biology Communications*, are being published at the beginning of January 1967 by the North-Holland Publishing Company. The former will appear once a quarter, and the latter will be bi-monthly but may later become a monthly.

A COURSE on gas chromatography–mass spectrometry has been organized by LKB Instruments, Ltd., in collaboration with the Gas Chromatography–Mass Spectrometry Unit of the University of Glasgow, and is to be held in the University of Glasgow from October 3. Further information can be obtained from Dr. P. R. Masek, LKB Instruments, Ltd., LKB House, 137 Anerley Road, London, S.E.20.

THE autumn meeting of the Chemical Society will be held at the University of Sussex during September 21–22. Further information can be obtained from the General Secretary of the Chemical Society, Burlington House, London, W.1.

THE seventh International Astronautical Congress will be held in Madrid during October 10–15. Further information can be obtained from the International Astronautical Federation, 250 Rue Saint-Jacques, Paris 5.

AN international technical meeting on "The Chemistry of the Aquatic Habitat" will be held at the Hydrobiological Institute, Nieuwersluis/Amsterdam, during October 10–16. Further information can be obtained from Dr. H. L. Golterman, Hydrobiological Institute, Rijksstraatweg 6, Nieuwersluis.

THE twelfth annual meeting of the Health Physics Society will be held in Washington, D.C., during June 18–22, 1967. Further information can be obtained from J. C. Villforth, Radiological Health Laboratory, 1901 Chapman Boulevard, Rockville, Maryland.

AN international meeting on "Liver Regeneration" will be held in Montecatini Terme during October 29–30. Further information can be obtained from the Scientific Secretary Office of Milan, 6 via Modica, Milan.

A SYMPOSIUM on "Electrode Processes", sponsored by the University Grants Commission, will be held in the University of Jodhpur during November 1–5. Further information can be obtained from Prof. R. C. Kapoor, Department of Chemistry, University of Jodhpur, India.

THE twenty-fourth annual Pittsburgh Diffraction Conference will be held at the Mellon Institute, Pittsburgh, during November 9–11. Further information can be obtained from Dr. Sidney Diamond, Applied Research Laboratory, United States Steel Corporation, Monroeville, Pennsylvania.

A CONFERENCE on "Small-angle Scattering of Electrons and X-rays", arranged jointly by the Electron Microscopy and X-ray Analysis Groups of the Institute of Physics and the Physical Society, will be held in the Institution of Electrical Engineers, London, during November 17–18. Further information can be obtained from the Meetings Officer of the Institute of Physics and the Physical Society, 47 Belgrave Square, London, S.W.1.

A SYMPOSIUM on "Fundamentals of Gas-Surface Interactions", co-sponsored by the U.S. Air Force Office of Scientific Research of the Office of Aerospace Research and the General Atomic Division of General Dynamics Corporation, will be held in San Diego, California, during December 14–16. The symposium will be concerned with the results of theoretical and experimental investigations of the following general topics: the surface and its characteristics; adsorption and reaction of gases on or with surfaces; scattering processes, including energy and momentum transfer at the gas-surface interface. Further information can be obtained from Dr. H. Saltsburg, chairman, General Dynamics—General Atomic Division, P.O. Box 608, San Diego 12, California.

ERRATUM. Figs. 2 and 3 accompanying the article "Extracellular Recording of Converging Input on Cortical Neurones using a Flexible Microelectrode", by L. T. Rutledge and J. A. Duncan (*Nature*, 210, 737; 1966), did not adequately show full details of the wave forms obtained in this experiment. Reprints with a clearer reproduction of the diagrams are to be had from Prof. L. T. Rutledge, Department of Physiology, University of Michigan, Ann Arbor, Michigan.

ERRATUM. In the article entitled "An Operator Model of Crossing-over", by Dr. H. L. K. Whitehouse (*Nature*, 211, 708; 1966), line 40 of page 711 should read "$\left(\frac{A}{A+B} = 0\right)$ shows the frequency with which hybrid".

JOHN DALTON AS A HISTORICAL FIGURE

By FRANK GREENAWAY

Deputy Keeper, Department of Chemistry, The Science Museum, South Kensington, London

ENDS are often beginnings as well, in the study of the history of science as in anything else.

The formal celebration in Manchester in September of the bicentenary of the birth of John Dalton (1766–1844) is likely to mark not only the end of a period of re-assessment of Dalton's life and work, but also the beginning of a new phase in the study of the chemistry of the nineteenth century. Other commemorations of men far surpassing Dalton in intellect and output have not promised so distinct a change in historical studies. Why make so bold a prediction ?

I suggest three reasons. First, the history of chemistry is in need of a radical re-appraisal. Two recent generations of scholars have gone back to the origins of scientific chemistry in the eighteenth century and have set out in some detail the work of the first men to bring high genius to bear on the problems of the constitution of matter: Black, Priestley, Bergman, Cavendish and the like, with the figure of Lavoisier nearly always somewhere in the picture. The composite picture has some completeness, and although a great deal of work remains to be done in correcting perspectives (as Smeaton has shown in his study of Fourcroy[1]) and in the editing of manuscripts (as Uno Boklund has done with Scheele[2]), there is no longer as much justification as there was for the one-sided concentration on eighteenth century chemistry of recent years. The chemistry of the past thirty years (that is to say, chemistry based on a unified quantum-mechanical view of matter coupled to new physical methods of observation, and new concepts of manufacture and social use) has apparently little obvious connexion with nineteenth century chemistry. The historical continuity needs to be re-presented if the modern chemist and the modern historian are to find any interest in new work in the history of chemistry between 1800 and 1930.

The second reason behind my claim for the importance of the Dalton commemoration is directly linked with the first. The effect of Dalton's atomic theory on nineteenth century chemistry was profound. By studying its interpretation by his contemporaries, its consequences, its modification at the hands of others, its competitors, its evolution into a comprehensive structural system, we can hope to follow at least one (possibly the only) continuous thread of thought through the chemistry of the nineteenth century. Moreover, and paradoxically as I shall show, it opens up new lines of sight on an almost unexplored field: the social and economic history of chemistry.

The third reason for the modern relevance of Dalton's life is the increasing interest in the methods of the scientist, work on which has by and large neglected the special problems of chemical thought. Students of scientific method have examined very closely patterns of enquiry in physics, astronomy and biology. The unthinking dismissal of chemistry as a rough and ready pursuit destined to be swallowed up in a generalized physics has been made quite out of date by new adventures of ideas in fields like molecular biology, where concepts of organization springing directly from an older chemistry have shown that chemical organization of matter has a significance which abstract physical thought cannot penetrate. If the state of chemistry in 1800 is compared with that in 1850 the differences are enormous, and nearly all have something to do with the factors which made up Dalton's theory of combination. Yet we cannot be clear or specific about how these changes were initiated in the minds of individuals. It might be argued that the mental processes of the eighteenth century chemists, few in number, remote in experimental resources from modern chemistry, could give us little help in understanding present-day chemical discovery. This is not true of the nineteenth century chemists who were making discoveries under intellectual and economic pressures which have many features similar to those of to-day. The chemical thought of the nineteenth century lies ready to be narrated and analysed just as much as does its practical achievement. Right at the beginning, provocative, even exasperating, is the mental development of John Dalton, putting to us the twin problems: what prepares a man to turn a picture of organization into a quantitative method, and what turns a quantitative formulation into a visual device ?

Dalton's achievement was a simple one: he showed how it was possible to relate microscopic measurements on substances entering into combination to a quantitative theory of microscopic organization. That is to say: elements consist of characteristic atoms; these atoms combine according to simple laws; therefore combination on the large scale will reflect these simple laws, and, vice versa, the examination of the actual massive behaviour of elements in combination will give information about the constituent atoms. The ultimate importance of this idea was not seen in Dalton's day, and its powerful secondary effects, which were not fully felt until well into the twentieth century, are not adequately recognized even to-day. It did, however, alter the whole of chemical thought within a few years of its widespread publication.

Four years elapsed between the time Dalton reported to a meeting of the Manchester Literary and Philosophical Society on October 21, 1803 (ref. 3), that he had achieved some success in a new speculation, and the time Thomas Thomson set out Dalton's contentions in his own *System of Chemistry*[4]. In the next year, 1808, Dalton published Part 1 of Volume 1 of his *New System of Chemical Philosophy*, that strange, ill-balanced book, which began as an attempt to emulate the amateur piece-meal physics of the eighteenth century and ended as a clumsy unfinished attempt to systematize the new professional chemistry of the nineteenth. Scattered through the later parts (Volume 1, Part 2 of 1810, and Volume 2, Part 1 of 1824) are some good observations, showing that Dalton had learned his chemistry tolerably well. The rest is of moderate merit, and already old-fashioned in style. But Chapter 3, "On Chemical Synthesis", of the 1808 part, in which Dalton explains his rules of combination, is the work of genius. Or at least, it seems so now. To Dalton's contemporaries, the atomic hypothesis was one to be approached carefully and critically.

The idea of the atom was as old as the Greeks; it had never really been lost to sight, and attempts to interpret the behaviour of matter in terms of particles endowed with appropriate mechanical properties had been made over and over again. Newton and Daniel Bernoulli had been able to explain a good deal in different ways by mechanical atomic hypotheses and there were a score of good chemists who had offered variants on an old theme. None, however, linked quantitative chemical behaviour with the essential corollary: the uniqueness of chemical species. Until Lavoisier, they could not. Nearest to success were the partly quantitative notions of Bryan Higgins and his nephew, William Higgins, but neither came anywhere near the universality of Dalton's theory[5].

The issues of the time were by no means clear or simple. Were compounds always formed in definite proportions ? Were organic compounds subject to the same laws as inorganic ? Were the so-called elements, the number of which continued to increase beyond belief as new discoveries were made, really distinct, or was there some

underlying simplicity? Was the behaviour of gases in any way connected with chemical constitution and, if so, what were its laws?

These were only a few of the problems. Dalton's theory did not solve them all, but it did give them a common basis, and although Davy, Wollaston, Berzelius and other leaders chose to adopt modifications of Dalton's ideas, rather than swallow them whole, the debates now had a point of reference. Supremely important was the fact that chemical analysis could now, through a system of proportions related to atomic weights, be given a unity it had never possessed before.

The laws of combination were so closely linked with atomism that it was easy to suggest that the atomic theory was directly inferred from them. Thomas Thomson had believed this, and for fifty years after Dalton's death it was good enough for most histories. Then in 1898, Henry Roscoe and Arthur Harden[6] examined the remains of Dalton's manuscripts and began a second phase in Dalton studies, by relating Dalton's published statements to the chronology of his notebooks. Their chief service was to show how important were Dalton's speculations about the nature of gases. Soon afterwards A. N. Meldrum[7] in a long series of papers urged that chemical evidence had in fact been in Dalton's mind, but that it was the result of experiments on the reaction between nitric oxide and oxygen which Dalton had carried out in his work on the composition of the atmosphere.

Nothing important was added to this in the next forty years. Historians of chemistry continued to treat the origin of Dalton's theory as a problem of no great importance, until in 1939 Partington[8] attempted to repeat Dalton's nitric oxide experiments, and showed that Meldrum's reliance on them was unjustified. Again little followed until J. B. Conant created the opportunity for a new enquiry by including the atomic-molecular problem in his series of *Harvard Case Histories*. L. K. Nash[9] wrote this case-history, basing the Dalton section on the older evidence. Soon after, in 1956, Nash[10] brought the Dalton problem back to the forefront by rejecting his earlier appraisal in favour of a novel and fertile suggestion. He analysed Dalton's work on gas-solubility, the work which has given rise to "Dalton's Law of Partial Pressures", had brought Dalton his early reputation, but had never been treated by historians of chemistry as at all closely connected with Dalton's chemical thought. Nash thus made Dalton the physicist the antecedent of Dalton the chemist, and in so doing made Dalton once again into a human figure, of unknown mental character, worthy of complete re-examination.

The material for a new biographical approach to the Dalton problem was reviewed in 1958[11], the stimulus given by Nash to consideration of Dalton the physicist suggesting that more attention be paid to Dalton's early work in meteorology, and on other phenomena such as the hydrological cycle.

Since that time many scholars have been preparing the ground for the commemoration to be held this bicentenary year. Much new work has been published already. Guerlac[12] has asked for reconsideration of the influence of Richter on Dalton, Brock and Knight[13] have examined the controversies over atomic theory in the mid-nineteenth century, Thackray[14] has shown that we need not be put off by the loss of much Dalton manuscript by enemy action in 1940, and has brought to light many unexamined Dalton sources. Dalton does not play the same kind of central part in early nineteenth century chemistry as Lavoisier in the generation before him, because the changes he brought about were neither so personal, so revolutionary, nor so clear-cut, nor was the main body of his work so comprehensive. Dalton was more of a catalyst than a reagent, but the several conceptual reactions catalysed by his ideas could well occupy scholars for a long time.

Some tasks are obvious: Partington's *History of Chemistry* has gathered a mass of facts which it will be the work of years to digest into critical specialist histories. The judgments and perspectives which this monumental work fails to provide are still to come, in almost every part of the vast territory which Partington has covered detail by card-index detail. There is still, however, another territory, wide open for exploration: that of the history of applied chemistry. Sherwood Taylor[15] tried to relate theoretical progress to industrial techniques, but his work is no more than an elementary introduction. Although there have been other works on some technical or economic aspects of industrial chemistry, no deep and detailed work has been written showing the relationships of theory, practice and social influence.

The irony is that Dalton made virtually no personal contribution to industrial chemistry, either by any discovery of manufacturing or economic significance at large, or by any service to the industries of Manchester, a fact which his prosperous commercial friends sadly regretted[16]. In another field Dalton unknowingly contributed to social change. As society was affected more and more by technical change, chemical factors came closer to daily life, in articles in common use and in the urban environment. The Pure Food Acts (1860 onwards) and the Alkali Acts (1864 onwards) are examples of the legislation which was made possible by the rise of analytical and control methods based on these same quantitative methods. One could follow this argument through to the present day, showing how the stoichiometric systems of nineteenth century chemistry still underlie most large scale practical chemistry.

I have said nothing about the rise of the theory of valency implicit in Dalton, which survives in so much of chemistry except at the theoretical frontier. The architectural chemistry which serves the molecular biologists is in direct line from Dalton and Wollaston. If physicists and biologists are rather over-fond of philosophizing about their most recent findings, chemists seem to philosophize too little. This is a pity, because the organization of matter, which is what chemistry is all about, is the key to so much that puzzles us in our material existence and, if research on the biochemical interpretation of mental processes comes to anything, may be the key to some of the operations of the mind.

Philosophically, the emergence of theories of the organization of matter at several levels and the study of the kind of discovery which must be made to stimulate thinking about organization present problems which bear on modern science as much as on older science. Dalton stands at the beginning of a new phase in the appreciation of material phenomena, and his thought, and the interpretation of his thought by others, deserves a deep study. It might well modify our ideas about the scope of scientific thought through the nineteenth century and even help us to understand our present thinking about matter at deeper levels than the atomic-molecular.

Be that as it may, the figure of John Dalton is likely to be looked at more closely now than ever before, to the great benefit of the yet unwritten history of chemistry as a major activity of thinking men.

JOHN DALTON THE ATOMIST

By DR. J. ROSE
Blackburn College of Technology and Design

"Thou knows . . . no man can split the atom"—DALTON

JOHN DALTON was born at Eaglesfield in Cumberland on September 6, 1766, of Quaker parentage. He himself remained a Quaker all his life, and his teachers, and friends during his childhood and early manhood, such as Elihu Robinson and John Gough, were Quakers. His father taught him arithmetic and navigation, while the wealthy Robinson interested him in meteorology and the blind Gough helped him with the studies of languages and mathematics. Dalton had the urge to teach at an early age. At the age of twelve he set up a school and at the age of fifteen he was working as an assistant in a Kendal school. He delivered, when twenty-one, a series of lectures on natural philosophy and was appointed in 1793 tutor in mathematics and natural philosophy at New College, Manchester, which was a dissenting institution fathered by the Warrington Academy. There he taught chemistry, using as his textbooks Lavoisier's *Elements* and Chaptal's *Chemistry*. He resigned from this post in 1800, and supported himself for the rest of his life by giving lectures and private tuition, while carrying out research.

To his research work Dalton applied simplicity of mind, boldness of imagination and systematic thinking. As an experimenter he was self-taught, and he used cheap materials and simple apparatus. His attitude was coloured by his preoccupation with meteorology. He kept a meteorological journal, beginning with observations at Kendal in 1788 and continuing until his death on July 27, 1844. It was this study of climate, water and air that eventually led him to the atomistic concept of matter. In his work which led towards his atomic theory Dalton worked quite independently from William Higgins (1762–1825), who was to make substantial contributions to an understanding of the forces between particles, the concept of multiple proportions and some modern aspects of reaction mechanism. Higgins did not attach any importance to atomic weights, which were to be a fundamental feature of Dalton's theory, nor did he propose any methods for their determination.

In order to follow the trend of reasoning and experimentation that led from a study of air and water to the atomic theory, it is necessary to consider certain observations made by Dalton in his *Meteorological Observations and Essays*, the first edition of which was published in 1793. Dalton asserted that pure air is an intimate mixture of "gasses" and the aqueous vapour is not chemically combined in the atmosphere, while vapour pressure is determined by the temperature alone. These concepts were quite novel and original, since hitherto air had been considered a chemical compound of nitrogen and oxygen, while water vapour had been considered a state of solution in the atmosphere, similar to that of salt in water, and that in some cases it could actually be transformed into air.

In his *New Theory of the Constitution of Mixed Aeriform Fluid and particularly of the Atmosphere*, Dalton criticizes Lavoisier's statement[1] that "the atmosphere is a compound of all the fluids, which are susceptible of the vaporous or permanently elastic state, in the usual temperature, and under the common pressure". According to Dalton, the last five words should be omitted. He elaborated his theory of mixed gases in four experimental essays read at fortnightly intervals to the Manchester Philosophical Society beginning on October 2, 1801, the starting point being Newton's concept of repulsive forces between particles.

In the first essay, he propounded a theory which is equivalent to what is now called the "Law of Partial Pressures" (William Henry restated this in 1804 as "every gas is a vacuum to every other gas"); he did not, however, use the term "atom" but instead "ultimate particle". The second essay was concerned *inter alia* with measurements of vapour pressures of water from 32° to 212° F, and calculations of these above 212° F by means of a rule; the former results lacked precision, while the latter were erroneous because they were based on an unsound rule. Of considerable significance was Dalton's finding that water vapour in the atmosphere behaves like any other gas in a mixture of gases.

In the third essay he showed that the quantity of water evaporating in a given time was proportional to the vapour pressure, while in the fourth essay he dealt with the expansion of different gases by heat and stated that all gases expand in the same way on heating. (It should be noted, however, that Charles, Gay-Lussac and Dalton share the honour of this discovery[2].) The ideas propounded by Dalton in the material published in 1801 were supplemented by a paper presented in 1803 on the diffusion of gases in which he showed that different gases mix uniformly. The quantitative aspect of what was to become known as Dalton's law of diffusion was not given until more than 25 years later by Graham.

Despite the ingenious and forceful presentation of the new theory of mixed gases, most of the leading scientists and textbook writers of the day reacted violently to Dalton's new ideas. Even his old teacher and friend John Gough was a persistent critic of Dalton's theory. Dalton's theory did indeed contain a serious flaw, because it was partly based on Newton's statical theory of repulsions; this accounts for the discrepancy between Graham's law of diffusion and the theory of mixed gases. The introduction of the kinetic theory of gases, as a result of the work of Dalton's pupil, J. P. Joule, removed some of the objections and clarified the subject of mixed gases. The important step in the evolution of the atomic theory was Dalton's attempt to adapt Newton's theory, in which air was considered as an element, by considering air as a mixture of gases, in order to explain gaseous diffusion. While in 1801 Dalton did not concern himself with particle sizes, two years later on the basis of chemical evidence—the formation of steam—he arrived at the conclusion which he later stated in his *New System of Chemical Philosophy* in the form[3] " . . . every species of pure elastic fluid has its particles globular and all of a size; but that no two species agree in the size of their particles, the pressure and temperature being the same". Oddly enough, Dalton anticipated Avogadro's hypothesis in 1801, but abandoned it[4], basing his change of mind on Davy's and Priestley's experimental results[5]. An entry in his notebook of 1803 contains an explicit denial of the "hypothesis". Despite this, the stage was now set for further developments culminating in the atomic theory.

It is clear from Dalton's notebook relating to September, 1803, as analysed by Partington[6], that he was aware of the following principles:

(*a*) Matter consists of atoms that are indivisible and indestructible.

(*b*) All atoms of a given element have the same invariable weight, whatever their combination with atoms of other elements or conditions, while atoms of different elements have different weights.

(*c*) The weight of a particle of a compound is the sum of those of its constituent atoms.

(*d*) The laws of fixed multiple and reciprocal proportions underlie the formation of particles composed of atoms of various elements.

(*e*) On the basis of the atomic weight of hydrogen taken as unity, it is possible to arrange those of other elements in an order of increasing values.

Indeed, on page 244 of his notebook an entry for September 6, 1803, gives the earliest known table of atomic weights. A printed report of a lecture given by Dalton to the Manchester Philosophical Society on October 21, 1803, gives another table of atomic weights on the hydrogen scale.

There were, however, a number of erroneous statements in Dalton's accounts of the atomic theory, such as that "nitrous acid" (N_2O_3) is a compound composed of NO and NO_2, while NO_2 represents "nitric acid". Apart from these and other relatively minor blemishes, the entries in his notebook in 1803 contained correct versions of the main part of his atomic theory; he was the first to use letter symbols for elements only. (Earlier William Higgins had assigned single letters to elements and compounds, but had been inconsistent in his notation[7].) For example, on page 361 of Dalton's notebook the characters for the elements are shown as follows: ⓗ or ○ for hydrogen; ○ for oxygen; Ⓐ or ⊙ for nitrogen; Ⓢ or ⊕ for sulphur. The symbols for compounds were: ○○ for water; ○⊙ for ammonia; ⊕○ for "sulphurated hydrogen"; ○⊕○ for sulphuric acid. As a result of Davy's intervention, Dalton gave a fairly complete account of his theory to the Royal Institution on December 22, 1803.

It is thus evident that Dalton was able to formulate his chemical atomic theory in 1803. The question arises, however, as to how Dalton actually arrived at his atomic theory. In his lectures to the Royal Institution in 1810, he attributed the origin of the theory to the study of mixed gases. But Meldrum[8] showed that Dalton had proposed a number of different accounts of the origin of the theory. He sometimes ascribed it to his study of Richter's table of equivalents, on other occasions he attributed it to his work on mixed gases, oxides of nitrogen, or olefiant gas and "carburetted hydrogen". A recent view[9] based on the discovery of a lecture syllabus of 1805 is that the study of the properties of water vapour and the calculation of the atomic weights of its constituent elements led Dalton to atomic weights of other substances.

Another plausible view, suggested by Nash[10], is that the immediate point of departure was the study of the solubility of gases in liquids, particularly since Dalton tried to explain why different gases have different solubilities. This opinion is supported by the fact that Dalton's paper on solubility, published in 1805, contains a table of atomic weights of elements and particle weights of compounds. This volume also contains a paper on the composition of the atmosphere, which implies the law of definite and multiple proportions based on the study of the oxides of nitrogen. Dalton's second book, *A New System of Chemical Philosophy*, published in three parts in 1808, 1810 and 1827, summarizes among other things his findings in connexion with the new atomic theory. The actual description of the atomic theory is given on pp. 211–220 of Part 1 which was printed in Manchester in 1808; the section is entitled "On Chemical Synthesis". The object of the book[11] is "to show the importance and advantage of ascertaining *the relative weights of the ultimate particles, both of simple and compound bodies, the number of simple elementary particles which constitute one compound particle, and the number of less compound particles which enter into the formation of one more compound particle*" (ibid., p. 213). He was successful in achieving his aims with the exception of the determination of formulae, particularly those of the oxides of nitrogen, as he admitted in 1827 (ref. 12). The reason for this was that Avogadro's hypothesis was required to obtain "an accurate knowledge of combining proportions".

The crowning achievement of Dalton's life was without doubt the formulation of the "chemical" atomic theory. He brought together quantitative chemistry and the atomic concept of matter, inferring microscopic properties from macroscopic measurements—the latter are themselves a reflexion of the atomic theory. Inorganic chemical analysis was given a rational basis by the prediction of theoretical compositions of substances and by a comparison of such with those experimentally determined. These ideas were later used in the realm of organic analysis and chemistry.

Dalton made other substantial contributions to science. In his lectures to the Manchester Literary and Philosophical Society (115 papers) he dealt with numerous topics including the elements of chemical philosophy, respiration and animal heat, aurora borealis, the absolute zero of temperature, steam engines, thermal expansion of gases, acids and bases, alkalinity of water, composition of steel and colour blindness. He was the first not only to prepare ammonium carbonate and to introduce the use of standard solutions in volumetric analysis, but also to demonstrate that the solubility of calcium hydroxide decreases with rise of temperature. One of the earliest definitions of the dew point was given by Dalton in 1799. He was able to disprove Rumford's theory that heat circulates in fluids by convection only, and showed that water is a poor conductor of heat. His procedure of adiabatic expansion was adapted in 1819 by Clement and Desormes to the determination of the ratio of specific heats of a gas. He contributed substantially to the elucidation of the composition of "inflammable air" by distinguishing between methane and ethylene (olefiant gas), and is also considered to be the discoverer of butylene. There is some inkling in his papers of polymerism (ethylene and butylene) and isomerism; he devised a tetrahedral formula for oxamide and postulated two different structural formulae for gelatine and albumin. The paper given on April 16, 1844, the last in his life, dealt with rainfall in Manchester during the preceding 50 years. In fact the last entry in his diary on July 27, 1844—the day of his death—was "little rain this day".

Dalton's services to chemistry were recognized and rewarded during his lifetime. In 1822 he was elected a Fellow of the Royal Society, and received the Royal Medal in 1826 with a eulogy from the then president, Sir Humphry Davy. Four years later Dalton was awarded Davy's place as one of the eight foreign associates of the Institut de Paris. In 1832 he became D.C.L. of Oxford, and a year later he was awarded a Civil Pension of £150 per annum (increased to £300 in 1836) and presented at Court. The University of Edinburgh conferred on him the degree of LL.D. in 1834, on the occasion of the meeting of the British Association for the Advancement of Science. The public contributed £2,000 to a marble statue of Dalton during his lifetime. He was the president of the Manchester Literary and Philosophical Society for 27 years until his death in 1844. He was given a public funeral, all the shops and warehouses in Manchester on the route to the Ardwick Cemetery being closed as a mark of respect.

BOOK REVIEWS

MEN WITH THEIR K'S

Memoirs of a New Man

By William Cooper. Pp. viii + 277. (London : Macmillan and Co., Ltd., 1966.) 25*s*. net.

THE heroes of the novels of the scientific administrator who writes under the name of William Cooper have now got to the top. No longer provincial schoolmasters or ambitious red-brick scientists, they have now all got their K's. Whereas *The Struggle of Albert Woods* showed the author as a scientific John Braine, except that he seemed anxious to demonstrate that scientists fight their way to the top in a more urbane fashion than arts men, his latest book is concerned with the intrigues that take place in Oxbridge colleges and the corridors of power. But again the author's irony and humanity civilize the struggles he portrays.

The narrator is a metallurgist, a professor and Fellow of Clarendon College, Oxford—a mirror image of a recent foundation elsewhere. He is also a part-time member of the National Power Board, a vast amalgam of the A.E.A. and the nationalized fuel and power industries. In its London headquarters, and in its research stations, the intrigues among the members of the Board are the outcome of the rivalry between scientists, engineers, and arts-trained administrators. The chairman is an ex-Civil Servant, extremely tall, brilliant, and quite ruthless, but with a contempt for the scientists and engineers that precludes attempts at simple identification.

At Oxford the intrigue is about the appointment of a research fellow, and about the part that non-scientific fellows should play in a college primarily founded to support science and technology. It is slightly complicated by a love affair between the successful candidate and the narrator's daughter. The latter's ambivalent attitude towards this affair and his understanding relationship with his daughter are portrayed with the author's characteristic charm, and so are the scenes of his family life with the usual aristocratic-born wife. Somehow even a description of the middle-aged couple, slightly drunk after a party, experimenting with one of the more difficult positions of the *Kama Sutra*, neither offends nor invokes any psycho-analytic speculation.

Unfortunately men at the top are not as interesting as men on the way up. The dynamism of the author's previous novels is lacking, and, although the conflicts of the new men and their methods of resolving them will amuse the "in group" of those who would have had the chance to participate in or observe such conflicts in real life, this novel will not be likely to have a wide appeal. It is well written, as all the author's novels are, but the story develops slowly and the characters, recognizable as types though they are, except for the narrator hardly come to life. The introduction at the end of a coronary as a *deus ex machina* to solve the Power Board's conflicts of personal power leaves unsatisfied the interest that has slowly been built up.

This is not so good a novel as William Cooper's previous novels and it is difficult to see where his hero can go from the top. But those who enjoy his writing and are fascinated by the subjects with which he deals will nevertheless eagerly await the next one.

AUSTEN ALBU

CHARGED PARTICLES

The Special Theory of Relativity

By J. Aharoni. Second edition. Pp. x + 331. (Oxford: Clarendon Press; London: Oxford University Press, 1965.) 70*s*. net.

THIS is the second edition of a book which was first published as recently as 1959. The new edition contains a much expanded treatment of relativistic charged particle electrodynamics, but is otherwise unchanged.

Aharoni's avowed aim is to make available to students with modest mathematical background the entire mathematical machinery which has grown up around the special theory of relativity and the Lorentz transformation. He has in mind the calculus of tensors, including the spinor calculus, and throws in some group theoretical aspects for good measure. In addition, he covers the formal aspects of the classical theory of fields, scalar and vector, together with the variational principle in its most general form, that is, allowing for the variation of the boundaries and the conservation laws which follow. Here and there, one finds allusion to quantum concepts; so in particular in the last, big chapter on spinors where such concepts as "Hilbert space" and "observable" are quite casually introduced.

The dust cover flap states that "as regards the physical content, it is assumed that the reader is already acquainted to some extent with classical dynamics, Maxwell's theory, and elementary quantum theory". One is tempted to add "knowledge of the physical content of the special relativity theory is also assumed". To be sure, there is an introductory chapter on space and time in inertial systems, in which the formalism of the Lorentz transformation and the standard implications is set up in some painstaking detail, but even here the emphasis is on formal aspects: discussion of the Michelson experiment, the Doppler effect, etc., is relegated to an appendix in small print. From there on, everything is formal and mathematical. The pace is quite leisurely and all calculations are certainly performed in very great detail. First we have the tensor representations of the three-dimensional rotation group, the covariant version of Maxwell's theory, and this is followed by a chapter on general field theory. Next is a chapter on relativistic particle dynamics which lays emphasis on electron theory, radiation reaction, and the Dirac model, and covers somewhat sketchily the Feynmann–Wheeler absorber model for radiative reaction. Rohrlich's recent contributions to the old self-energy and stability problem for the point electron are quite adequately covered, but it seems odd that the truly covariant criterion for radiation is missed out. I found this much the best part of the book.

There is a brief chapter on relativistic hydrodynamics and then a long chapter on spinors. The relationship of the unimodular group to the Lorentz group is spelled out without previous careful elucidation of its relationship to the rotation group in three dimensions. This is worked in piecemeal. The discussion of ray representations is rather unsatisfactory and the "infinitesimal" developments are sketchy. Still, the technique of the relativistic spinor calculus ("dotted and undotted" spinors) deserves wider dissemination, and this book covers the ground in its formal aspects. Many readers perhaps may still ask "What is it all about?"

There will probably be students who will find this book very helpful, and for others it may act as a curtain raiser. I find myself at variance with the author's declared sentiment that painstaking attention to the calculational aspects of the formalism *ipso facto* paves the way to an understanding of physical theory.

Layout and printing are as one has come to expect of the Clarendon Press.

S. ZIENAU

GEOMORPHOLOGY MEDLEY

Précis de Géomorphologie

Par M. Derruau. Quatrième edition. Pp. 415+61 planches. (Paris: Masson et Cie., 1965.) 45 francs.

Principes et Méthodes de la Géomorphologie

Par J. Tricart. Pp. 496. (Paris: Masson et Cie., 1965.) 84 francs.

Techniques in Geomorphology

By C. A. M. King. Pp. ix+342. (London: Edward Arnold (Publishers), Ltd., 1966.) 40*s*. net.

THE name of a science is no doubt best understood as what scientists working in the field do; but it is notorious that "geomorphology" in its roots lends itself to an amorphous spread that spills over into a number of orthodox sciences, and not all geomorphologists speak the same language. Tricart and King are scarcely in direct line of descent from Derruau, or quite in harmony with one another.

Derruau's book, in its fourth and much revised edition, accepts geomorphology to be in essence physical geology. With only slight changes in balance it might well be recommended as an introductory text for would-be geologists. It begins with problems of crustal tectonics, including discussion of isostasy, continental drift, cratonic and geosynclinal contrasts, and orogenic cycles, as a basis for detailed study of the growth of landforms—although in doing so it assumes a knowledge of Earth structure that perhaps is too much to expect in junior students. Nearly half the book is very thoroughly descriptive, with some analysis, of the processes of erosion, particularized in chapters on the work of rain and rivers (Davis a little obtrusive), ice, wind, and the sea. An attractive feature of the description is the way in which kinds of landforms are correlated with the variable interaction of agents, when climate controls process. The influence of rock-foundation on relief is dealt with in a section that combines the elements of petrology with primary igneous forms, basins of sedimentation and classes of sediments, metamorphism, and tectonic structure; and the author does not overlook the significance of geological history, revealed in stratigraphy, in an understanding of the evolution of landscape. The many illustrations are orthodox but excellent in relevance and quality; and altogether the book is impressively attractive and readable, if not quite what a geologist would be prepared to call geomorphology.

Tricart, not always unemotional in his dialectic—he is bitterly critical of the malign influence exerted by the inductive speculations of W. M. Davis—defines the unexceptionable central concern of geomorphology as the study of the relief of the Earth's surface; but in doing so he relates geomorphology so closely to other disciplines that he takes over from them topics that normally would interest pedologists, hydrologists, sedimentologists, and even botanists. He writes as a practising geologist who takes for granted the foundations of physical geology on which a growing geomorphology rests. The relief of the Earth's surface includes relief in past times, and palaeo-geomorphology embraces stratigraphical correlation, including correlation esoteric in palynological, tephrological, and geochronological techniques.

This said, Tricart is more concerned with principle and method than with fields to be covered, his central theme being the need for system and order in the organization and explanation of what the geomorphologist observes. System, however, while acceptably justified by argument on what ought to be done, tends to be imposed and formal. This is notably so in a "taxonomic" classification of the units of geomorphological study into eight grades of magnitude from continents and oceans to yardangs and joint-partings and mineral decay, and in a gradation of events (secular orogenies, catastrophic landslips) in segments of a time-scale ranging from geological eras to hours or minutes. He lays much emphasis on the uses of maps and aerial photographs, and on ways of constructing maps so as to increase their usefulness and content of information, and map drawing is formalized in an exhaustive array of symbols to cover almost all possible kinds of landform elements. Statistics and morphometry are given a place as new techniques, but the treatment is slight.

Tricart is stimulating, not to say provocative, in his polemics. He builds a framework into which geomorphology may be put. He brings his own kind of order to what has hitherto been a certain waywardness in method. He rightly directs attention to the need for discipline in geomorphological practice and theory. And he summarizes methods appropriate to a variety of geomorphological problems. It is disappointing that in his analysis of actual examples and in the use of illustrations he does not always reach the measure of his intention or discriminate finely enough between the important and the relatively trivial, and that in specifying the bounds and contacts of geomorphology he follows trails beyond its limits and blurs its field by making it accretory and diffuse.

King's book, although covering part of the same ground, is far more modest in both manner and content. In the result it is far more instructive and substantial. Its bias is towards a geomorphology that on the one hand does not lean unduly on a limited physical geology, and on the other avoids plunging too deeply into geophysics and stratigraphy and petrology. It brings out the relationship of structure and process with great clarity, constantly doing so by reference to appropriate examples that give reality to theoretical interpretation. Geomorphology emerges as a tracing of the evolution of the existing landscape through the integrative correlation of a great variety of landforms, although the main objective of the book is neither to define the science nor to provide a conspective summary of its range. At the same time, King is fully aware of the diverse approaches which geomorphologists may follow, and her exposition offers instances of most of them as they are revealed in real examples.

The central purpose of the book, however, is to discuss techniques, from field surveying to the use of models. An early chapter stresses the importance of direct observation of form and character in the analysis of landscape, and of observation supplemented by the skilled use of maps and aerial photographs, by the need commonly met for a refined contouring, and by excavating and sampling. A succeeding chapter similarly stresses observation and experiment in the study of geomorphological processes—river flow and river transport, nivation and glaciation, periglacial and permafrost features, mass movement in avalanches and landslips, wind transport, and wave and tidal action. Discussion of the ways in which models may throw light on the correlation of theory with observation and experiment includes critical comment on the propriety of applying results from conceptual and scale models to processes in nature, and very full descriptions of actual models and their advantages and limitations. A chapter on cartographic and morphometric analysis as a systematization of a multitude of landform elements, and sediment analysis as a guide to erosion and transport, leads to an assessment of the value and significance of statistics in geomorphology and of the validity of geomorphological conclusions based on statistical pointers.

Parts of King's book are a little uneven in being unusually elementary or unusually specialist; and some of the examples quoted need more rigorous treatment than they are given. But to cavil at this page or that would be ungracious, when the bringing together of so much information and guidance, simply and directly put, offers nothing but good to the young student as much as to the professional geomorphologist.

T. NEVILLE GEORGE

SCIENTIFIC ENDEAVOUR AND ACHIEVEMENT

Charles Scott Sherrington

An Appraisal. By Ragnar Granit. (British Men of Science.) Pp. xii + 188 + 14 plates. (London and Edinburgh: Thomas Nelson and Sons, Ltd., 1966.) 42*s*. net.

THIS book is by an eminent Scandinavian physiologist on a great British physiologist. It was written in English and is not a translation; its smooth reading reveals Prof. Granit's command of the language. He is the Director of the Nobel Institute for Neurophysiology in Stockholm, and he twice worked in Sir Charles Sherrington's laboratory in Oxford in the late twenties. At that period Sherrington, freed from exacting commitments such as being President of the Royal Society, was able to devote much of his time to an active but not too large Honours School and to a group of graduate research workers, many of whose names are to-day familiar in neurophysiology and neurology. His work then was concerned with details of the reflex activity of the spinal cord, including the part played by the muscles and the synaptic connexions of their nerve fibres in this activity.

Sherrington (1857–1952) felt that posterity should judge a man by his work and he expressed dislike of certain long detailed biographies, hoping that nobody would attempt such an exercise on him. This wish has so far been respected. It is true that there are excellent obituaries in the journals, but further biographical writing has been tackled differently. In E. G. T. Liddell's absorbing book *The Discovery of Reflexes*, the state of nerve physiology and histology is described as it was before and during Sherrington's work for *The Integrative Action of the Nervous System*. Granit sets out to emphasize how some of the main problems of neurophysiology stem directly from what Sherrington did.

After a brief biographical and historical chapter, Granit goes on to deal with the concepts underlying Sherrington's work, and particularly with inhibition in the nervous system regarded as an active process, which is one of the main landmarks with which Sherrington's name is now associated. His work on this subject is described, as is that of his pupils and contemporaries. Then come chapters on the wider outcome of this pioneer work. First, there are the advances made possible by the development of amplifying devices; particularly by Adrian (Sherrington's joint Nobel Laureate) in recording single nerve impulses. Then comes the investigation of individual parts of the reflex arc by the use of microelectrodes. Eccles, by developing this technique, was able to penetrate single motor horn cells in the spinal cord and so get information about the activities of the synapses of an individual cell. This continued Sherrington's "pulling to pieces from the top downwards", but he also prophesied that "the elemental may not prove to be the simple" and one of the problems of to-day is, so to speak, to put the animal together again. Something of this has been taking place in Granit's own laboratory and he writes of the work on reflexes and motor control, and particularly on muscle spindles, which Sherrington had described in 1894.

The final chapter on Sherrington's writings is largely taken up with a summary of *Man on his Nature*. This is not an easy book to read, but it is lit up with passages of beauty and insight. There are also quotations from Sherrington's book of poetry *The Assaying of Brabantius*. For Sherrington, writing was always bound up with the desire to make everything "absolutely clear", and he maintained that this could be done more precisely in Latin or French than in English.

Granit's book is one to read at leisure and from which to allow something of the whole personality of Sherrington to emerge, including his capacity for the accumulation of knowledge, the power to ask the right questions in physiology and the skill to get the answers, all in an individual who was a poet, something of an artist, a lover of nature and a man who could command devotion and respect from those who came in close contact with him and worked under him. SYBIL COOPER CREED

HOW TO SUCCEED IN PAINTING

The Application of Surface Coatings

(Paint Technology Manuals, Part 4.) Pp. xiii + 345. (London: Chapman and Hall, Ltd., 1965. Published on behalf of the Oil and Colour Chemists' Association.) 35*s*. net.

The Testing of Paints

(Plant Technology Manuals, Part 5.) Pp. viii + 171. (London: Chapman and Hall, Ltd., 1965. Published on behalf of the Oil and Colour Chemists' Association.) 35*s*. net.

"'TIS a Dutch proverb, that 'paint costs nothing', such are its preserving qualities in damp climates". This quotation from Emerson serves as a heading to the foreword of Part IV of the Paint Technology Manuals published by the Oil and Colour Chemists' Association. The proverb holds only to the extent that the paint is of good quality, and that the surface has been prepared and the paint properly applied. While it is easier to succeed in painting than in business without really trying, the chances of success are enormously increased by treating the exercise in a careful, planned scientific manner.

Fortunately, this has been realized for many years in large-scale factory application of paint, and the realization is spreading to still wider circles of paint users all the time. The present two volumes, covering the whole of paint technology, should do much to aid the process of education.

Part IV continues the system of earlier volumes whereby each chapter is written by a specialist in that topic. By far the largest portion (280 pages) is concerned with various techniques for the industrial application of paint, and the application of decorative and protective coatings for constructional materials gets only 50 pages. After a chapter on equipment for industrial finishing, the material is dealt with in terms of the substrate to be coated, as is almost inevitable in view of the very specific problems found in each industry.

A severely practical outlook permeates the book, and those who expect to find reasons why things happen, or should be done, will seldom find them here; it is essentially a plain man's guide, and at that level will serve a very valuable function. But it is disappointing to find a book devoted to the application of surface coatings that completely ignores any treatment of the rheological properties of paint, and gives no background data on adhesion. Some theoretical background is given in the chapter on industrial metalware, but otherwise such material is conspicuous by its absence.

Part V, *The Testing of Paints*, differs from the other volumes in that it is essentially the work of one man, F. G. Dunkley, and the treatment is more unified. After a short chapter on test methods for production quality control, there follow chapters on tests for basic properties and tests for specific properties. Basic properties include viscosity, gloss, hardness, flexibility, durability and adhesion, while specific properties cover chemical resistance, fire retardance, electrical properties, basic paint tests and film thickness (surely this is a basic property ?).

The emphasis is on those methods of test in widespread use in Britain, but due reference is made to other tests where these have been found to be useful; an appendix collates the relevant American Society for Testing Materials, British Standard and Ministry of Defence (DEF) specifications. There is a fairly full bibliography,

but this loses much of its value by the unsystematic way in which the papers are listed. A very wide range of test methods is covered, and there will be few topics on which guidance cannot be found.

There will undoubtedly be a call, in due course, for second editions of these and other volumes in the series. When these are being considered, it would be well to consider anew the purpose they are designed to serve. When the series was conceived (and indeed during the repeated childbirths of successive volumes), the aim was to cover the requirements of the City and Guilds paint technology courses. There have been major changes in the educational pattern for paint technology since then, and the process of change is still taking place; it is likely that a rather different manner of treatment will best meet the changed circumstances. One would like to know whether the series is aimed at the technician or the technologist, for they have different needs, and whether there is sufficient scientific background material.

L. VALENTINE

ASPECTS OF TITANIUM CHEMISTRY

The Organic Chemistry of Titanium

By Raoul Feld and Peter L. Cowe. Pp. viii+213. (London: Butterworth and Co. (Publishers), Ltd., 1965.) 52*s*. 6*d*.

IT is estimated that the number of scientific publications doubles every 15 years. Quite clearly the modern chemist must grow to rely more and more on good review articles and review texts if he is to keep abreast of developments within his subject or even within his branch of the subject. This book has been planned as a comprehensive review of the chemistry of organic titanium compounds. Its value will consequently be a function of the success with which the literature has been covered and assessed critically.

The coverage of the literature is certainly impressive. The title of the volume could be more informative, since "organic titanium compound" is taken to include all titanium compounds of which carbon is a constituent, not merely those in which it is the ligand atom. Thus, apart from the obvious interest of the book to workers in organo-metallic chemistry, the chapters on alkoxides, halide complexes and low valent titanium compounds will be welcomed by inorganic chemists. It is regrettable, however, that the authors have not been more critical; much of the text reports rather than reviews the contents of the literature. To quote three examples from several, the status of *bis*(*cyclo*pentadienyl) titanium was in question when the book was written (the situation is now much clearer), yet the reader is given no indication of this fact. Also, it is likely that the concept of oxidation number is of doubtful value for compounds such as *tris*(2,2′ bipyridyl) titanium which are too readily accepted at their face value in Chapter 9. The diagram on page 7 would probably have been better omitted.

The book has three particularly strong features. The coverage of the vast patent literature is laudable. The authors have managed to filter out the more optimistic claims and report only those patents which substantiate their conclusions with at least a minimum of chemical or physical data. Since a certain proportion of the work in the field of titanium chemistry in the future may consist of more detailed examination of known compounds, the excellent tabulations of these compounds together with their physical properties are likely to place many future workers in the authors' debt. Predictably the uses of titanium compounds have been emphasized. The chapters on titanium co-polymers and Ziegler catalysts are among the strongest in the book. It was the more surprising therefore to search in vain for an assessment of titanium tetrachloride as a catalyst for the Friedel–Crafts reaction.

The book should find a place in most chemical libraries. The price is not excessive by present-day standards. Misprints are few and are confined almost exclusively to equations and formulae. The failure to report authors' initials in the references may give rise to some minor irritation, but both author and subject indexes appear to be comprehensive and accurate.

WILLIAM R. MCWHINNIE

STEROID RESEARCH

Methods in Hormone Research

Vol. 5. Steroidal Activity in Experimental Animals and Man, Part C. Edited by Ralph I. Dorfman. Pp. xiii+342. (New York: Academic Press, Inc.; London: Academic Press, Inc. (London), Ltd., 1966.) 104*s*.

EVER since the synthesis of norethisterone (17α-ethynyl-17β-hydroxyestr-4-en-3-one), a search has been made for other useful progestational agents. Miyake and Rooks make a valuable contribution to this volume with a well presented review of those progestational steroids which have become available during the past few years. Data are provided showing the influence of nearly every substitutional site in steroids on the physiological activity of these progestational materials.

The chapter on anti-gonadotrophic steroids by Dorfman and Kincl is also a useful contribution. It deals mainly with the relationships between the structure and activity of those steroids which inhibit the biosynthesis, and sometimes the release, of gonadotrophins. The authors point out that work involving the parabiotic rat technique has certain limitations, and does not allow selective measuring of the inhibition of follicular stimulating hormone in the rat—if indeed there is any selective differentiation from luteinizing hormone to be measured. The introduction to this chapter unfortunately gives the impression that anti-gonadotrophins operate mainly at the pituitary rather than the hypothalamic level. Nevertheless, valuable data on the inhibition relationship are included. This sort of work and that of Miyake and Rooks with the progestational steroids prove that the combination of organic chemists, endocrinologists and physiologists is extremely powerful. Success in dealing with the problems of over-population will surely only be obtained by more work of this kind.

Other chapters in the book provide useful information on the effect of steroids on the central nervous system, the treatment of human malignancies with steroids, and the relative potencies of androgens. The editor is to be congratulated for supplying once again a valuable reference book. It is an excellent addition to the earlier volumes of the series.

D. EXLEY

SECONDARY METABOLISM

The Biosynthesis of Natural Products

An Introduction to Secondary Metabolism. By John D. Bu'lock. Pp. x+149. (Maidenhead: McGraw-Hill Publishing Company, Ltd., 1965.) 28*s*.

THIS book meets a need which has been increasingly felt by scientists interested in natural products. The title is somewhat misleading in that the book is not concerned with the main metabolic pathways by which amino-acids, fats, and carbohydrates are synthesized in the cell or broken down. Its subject, which has been of special interest to the organic chemist and less so to the biochemist, is the formation of a great variety of compounds such as terpenes, alkaloids, antibiotics, and a variety of other substances, chiefly by green plants or fungi. In this field of science enzyme methods have been little used, and investigations are increasingly based on the use of putative labelled precursors in whole cells or whole organisms. In this secondary metabolism, the substances concerned are

not functional constituents present in all plants, but can only be obtained from particular species of plants. Apart from this restricted taxonomic distribution, these compounds often have no obvious metabolic function but represent a fascinating challenge to the organic chemist, to the plant biochemist, to the taxonomist and to any scientists interested in the tremendous variety of chemical substances which are produced by this "secondary" metabolism.

Apart from a full account of our general knowledge in this field, the use of plant genetics in secondary metabolism is described in detail. Dr. Bu'lock also links the specific problems of secondary metabolism with general enzymology where this is appropriate. The volume represents a comprehensive and at the same time concise account of this increasingly important field. It is, however, written primarily from the standpoint of the organic chemist interested in natural products, and assumes in the reader a fairly sophisticated knowledge of reaction mechanism and modern theoretical organic chemistry. It is doubtful whether the botanist or mycologist whose chemical knowledge may have been acquired 15 or 20 years ago will find it easy to follow the detailed chemical arguments which are used. The author is, however, careful to point out the limitations of our present technique, and the fragmentary character of our knowledge, and indicates clearly where further progress may be expected.

A. NEUBERGER

STICKINESS AND CANCER

Hyaluronidase and Cancer

By Ewan Cameron. Pp. xiii + 245. (London and New York: Pergamon Press, Ltd., 1966.) 50*s*. net.

DR. CAMERON'S stimulating book presents a thesis which is stark in its simplicity. The excessive secretion of hyaluronidase is the beginning, the middle and the end of the problem of cancer.

According to Dr. Cameron, neoplastic cells arise as the result of the interaction of any carcinogenic stimulus with the protein–mucopolysaccharide ground substance, as a result of which the latter becomes increasingly viscous and impermeable. Adjacent normal cells attempt to maintain their normal environment by the increased release of hyaluronidase. "Each cell in the body is firmly embedded in a sticky viscous cement of ground substance" which is attached by hyaluronidase. Contact between the cells is reduced and this in turn permits or stimulates cell division. The preferential nutrition of tumour cells is the result of local increased stromal and capillary permeability evoked by hyaluronidase secretion. Malignant infiltration and the formation of metastases are likewise due solely to the action of the enzyme on the surrounding normal tissues and the walls of blood and lymph vessels.

Dealing first with the application of Dr. Cameron's ideas to carcinogenesis, it is very difficult to understand how his mechanism of carcinogenesis could account for the *in vitro* malignant transformation of normal cells by viruses, carcinogens, X-rays or "spontaneously". Dr. Cameron appears to be either unaware of, or to ignore, the considerable body of work published in recent years establishing the existence of tumour-specific antigens in many experimentally induced animal tumours, and the possible role of the immune response in the development of these tumours.

On the subject of the irreversible nature of the neoplastic transformation, the author considers that it is clearly a matter of cellular inheritance, but rejects the view that interaction between DNA and a carcinogen is involved, even in the initiation, with the rather cavalier phrase "there is not a shred of evidence to support its validity". Potter's deletion theory and Warburg's hypothesis are not mentioned.

When it comes to the role of cell contact in regulating cell proliferation, the author probably finds more common ground with other workers in this field. He carries the cell contact mechanism of cell proliferation much further than most, particularly when he ascribes loss of cell contact solely to the secretion of hyaluronidase. This enzyme, incidentally, has so far proved remarkably ineffective in dispersing cells in tissues. Tumour cell nutrition is dealt with without mentioning the greater capacity for glycolysis or other changes in metabolic processes which have been extensively investigated.

The release of hyaluronidase by tumour cells has been considered by many investigators to play a part in malignant invasion, but the evidence is contradictory, and Dr. Cameron's review of it does not convince this reader that hyaluronidase is the only, or even the main, enzyme system contributing to invasion. Assessing the evidence is not made easier when the role of proteolytic enzymes is dismissed in four lines.

Dr. Cameron's arguments are presented very clearly and with a coherence which is, perhaps, gained at the cost of omitting a considerable amount of established work which does not fit in with his thesis.

This book should serve a useful purpose by stimulating many investigators in the field of cancer research to re-examine carefully the basis of many of the concepts currently held. The author has made a very extensive survey of the literature pertaining to the role of hyaluronidase in cancer, which is extremely useful. G. C. EASTY

BEHAVIOUR AND NUCLEIC ACIDS

Macromolecules and Behavior

Edited by John Gaito. Pp. ix + 197. (Amsterdam: North-Holland Publishing Company; New York: Appleton-Century-Crofts, a Division of Meredith Publishing Company, 1966.) 29 guilders; 58*s*.

THIS little book has brought together some fascinating articles in a rather unusual field. They are directed in the main at the role of RNA and DNA in determining behaviour, although nearly all the experimental evidence relates to the changes in the macromolecules following on experimental procedures. Except in the last chapters, where K. H. Pribham and others present their theoretical treatment of the basis of memory, there is often a fairly tenuous connexion between the experimental data presented and rather gross behavioural patterns. Nevertheless, the book has gathered between its covers a very valuable and readable series of papers.

The chapter by Ochs on axoplasmic flow is an excellent summary of the recent work on transport of molecules of many kinds along the axoplasm. The chapter by Pevzner is a review of, among other topics, cyto-spectrophotometric methods; in the original material presented, it reveals the great extent to which such techniques have developed in the Soviet Union. Pevzner's chapter is the most provocative, as he modestly, but thoughtfully, raises the question in his brief summary as to just what the relationship is between the nucleic acids and behaviour, and just how far the biochemists can at present go in finding a meaningful answer. The difference in the time scales between the laborious and time-consuming procedures of the biochemist on the one hand, and the speed of action in nerve cells as demonstrated by the electro-physiologist, on the other, is so enormous that one rightly asks: can the two approaches ever meet?

In spite of such difficulties, this book shows that in a surprising number of instances correlation is possible, even with the attempt to show that treatment of certain types of elderly individuals with RNA leads to an improve-

ment of their general condition and, less convincingly, their memory functions.

The book is the outcome of a symposium held in 1964. The contributors to the symposium have clearly had ample time to rewrite their communications and bring them and their bibliographies up to date. While there may be a good reason for it, one name seems to be a regrettable omission from the list of contributors—Hydén of Gothenberg. His work is cited in some context or other by almost every author, and rightly; he is the pioneer in this field and should surely be regarded as the father of many of the current ideas and techniques. It would have been a pleasing gesture if this admirable little book had been dedicated to him.

J. L. MALCOLM

Human Geography

By Aimé Vincent Perpillou. Translated by the late E. D. Laborde. (Geographies for Advanced Study.) Pp. xx+522+37 plates. (London: Longmans, Green and Co., Ltd., 1966.) 50*s*. net.

THIS book could have been written only by a great scholar, for it fills its pages with example after example of man's evolution, his adaptation to environment, the techniques he has evolved to emancipate himself from that environment and in his manner of settlement. The width of Prof. Perpillou's knowledge is quite astounding. He has cast his net throughout the world in his apparently effortless quest for illustrations of man's conditions. Especially noteworthy are his examples drawn from otherwise largely inaccessible sources. In places one might wish perhaps that academic axes were not being ground quite so noticeably—for example, in his attitude to Huntington and Meitzen.

British students may be surprised by the socio-anthropological point of view of the work, though this is much in the tradition of Brunhes and de la Blache. Certainly those familiar with recent publications by British geographers on the topic will here find a totally different conception of the subject. This method is shown at its best in the sections on tropical lands where the interaction of social anthropology and more "civilized" geography is most fruitful.

One major criticism is the paucity of illustrations of a more graphic nature, especially of locational maps. The publishers and editor of the series are, however, to be congratulated on having had the initiative to invite a doyen of French geography to write specifically for English-speaking students. The author has undoubtedly set a very high standard of learning for his readers.

R. T. JACKSON

Open Tubular Columns in Gas Chromatography

By L. S. Ettre. Pp. xix+164. (New York: Plenum Press, 1965.) $4.95.

THE dramatic increase in the volume of literature devoted to gas chromatography has made the investigation of any one aspect an arduous task in terms of the effort required to abstract relevant information. Monographs produced by acknowledged experts in a given field are, in this respect, particularly welcome. This book falls into such a category. Written essentially for the practising gas chromatographer, the book is confined to practical details. When theory is introduced, the frills of mathematical derivation are limited and only those definitions and equations necessary for the proper understanding, evaluation and operation of the technique are introduced. In the simple presentation the two typographical errors which occur in equations (18) and (24) are easily recognized.

After the brief historical introduction and statement of definitions, the practical implications of the Golay equation are discussed and comparisons made with conventional packed columns together with other factors such as sample capacity. Small-bore open tubed columns (also referred to as capillary or Golay columns) have not been used as extensively as packed columns except where necessity has dictated, no doubt because of the relative ease with which the latter may be made. The author's simple account of the various techniques which may be used to coat the internal walls of the column should help to dispel any mystery associated with the process. Among other factors, surface effects are considered in the preparation of the column, both in their elimination to reduce tailing, and deliberate introduction to increase surface area and consequently stationary phase loading. The consideration of the relatively new technique of "packed capillary" columns in which some form of internal surface coating is used to obtain a relatively large surface capacity of stationary phase follows as a natural corollary.

The very small sample sizes which are necessary in order to avoid overloading of conventional open columns inevitably involve some modifications to the sample inlet system. The fourth section deals with these requirements in the gas chromatographic system and includes such important matters as stream splitting design.

After the listed bibliography, which contains 286 references, a supplement is appended, giving details of the various methods which may be used for the calculation of the "air peak" time.

E. A. WALKER

Plasma Diagnostic Techniques

Edited by Richard H. Huddlestone and Stanley L. Leonard. (Pure and Applied Physics: a Series of Monographs and Textbooks, Vol. 21.) Pp. xii+627. (New York: Academic Press, Inc.; London: Academic Press, Inc. (London), Ltd., 1965.) $19.50.

As pointed out in the introduction to this book, progress in experimental plasma physics depends on the development of suitable diagnostic techniques. Such development has been rapid, and it is convenient to have a single volume such as this in which most of the commonly used methods are described.

The book consists of an introduction and twelve review articles, each by an author who has specialized to some extent in the technique described. Separate chapters cover basic macroscopic measurements, magnetic probes, electric probes, spectral intensities, line broadening, optical and ultra-violet techniques, X-ray spectroscopy, far infra-red measurements, optical interferometry, microwave techniques, and particle measurements. Most of these chapters form natural subdivisions, although that on X-ray spectroscopy could have been more naturally and economically divided between the chapter on optical and ultra-violet techniques and that on spectral intensities, which contains a useful section on the various models of non-thermal plasmas, besides much else relevant to X-ray work. Each chapter is followed by a very complete bibliography. This layout suffers from the disadvantage that different methods of measuring a given parameter appear in nearly every chapter, and it would be difficult to choose the best for a given experiment without reading the entire book, despite the comprehensive index. It does, however, permit all the techniques included to be discussed systematically. There are, of course, some omissions. For instance, it is surprising that the chapter on optical and ultra-violet techniques makes no mention of the special properties of interferometers when high light-gathering power is required. Relatively small space is given to techniques based on the scattering of laser-generated radiation, but this is almost certainly a result of the rapid progress made with these methods since the volume was compiled. In general the book contains a considerable quantity of information, and should be a useful addition to the available literature.

D. D. BURGESS

MEETINGS

FERTILITY

THE annual conference of the Society for the Study of Fertility was held at Churchill College, Cambridge, during July 5–9. The meeting opened with a group of papers on the interactions between foetal and maternal tissues in early pregnancy. Oxford workers have studied the transplantation of eggs and trophoblast in the hamster and the mouse; they showed that when trophoblast tissue was transplanted into the testis some trophoblast cells reached remote areas of the host, apparently by migration along blood vessels (D. Billington). By the same technique they were able to distinguish between the trophoblastic and decidual contribution to the luteotrophic activity of the pregnant uterus (D. R. S. Kirby and T. Cowell). The enzyme and morphological changes involved in implantation in mice and rats were described in great detail (A. McLaren and C. Finn; B. L. Lobel, E. Levy and M. C. Shelesnyak) and some factors affecting early embryonic mortality in the pig were discussed (M. Phillippo).

Great interest was shown in techniques designed to facilitate the study of isolated endocrine organs and tissues; whole rat ovaries maintained in organ culture (T. Fainstat), equine granulosa cells which produced progesterone in tissue culture (C. P. Channing) and autotransplants of sheep ovaries to the neck (J. R. Goding).

The second session was devoted to a symposium on radiation effects on the reproductive system, under the chairmanship of Prof. D. Lacy. The first two papers (P. Lindop; H. M. Beaumont) described work on the radiosensitivity of oocytes and other cell types in the ovary of the mouse, an animal which has been intensively studied in this respect, and the remaining papers were concerned with irradiation effects in the male. These effects have been studied in considerable detail in the rodents, and similar work has now been extended to other species, including the goat and man (E. W. Hupp). Work with human volunteer subjects (C. A. Paulsen and H. M. Gandy) has demonstrated the extreme sensitivity of the human testis to irradiation, and has emphasized the reciprocal nature of the relationship between gonadotrophin output and germinal epithelial function. At the ultrastructural level, X-irradiation has been used in studies of organelle induction and differentiation during spermatogenesis in the grasshopper (T. N. Tahmisian).

The third session opened with a group of papers on species other than common laboratory or domestic animals. They were concerned with comparative aspects of reproduction in the chinchilla (B. J. Weir), the squirrel monkey (J. P. Bennett) and some of the larger Felidae from the collection of the Zoological Society, Regent's Park, London (R. M. F. S. Sadleir). This session also included reports on such diverse topics as the descent of the testes in the grey seal (K. M. Backhouse and H. R. Hewer), a species with a non-scrotal testis, and the influence of such environmental factors as pasture management and outbreaks of myxomatosis on reproduction in the wild rabbit (H. G. Lloyd), and the decidual changes associated with "endometrial cups" in some Equidae (J. M. King). The session concluded with three papers on the application of neurophysiological techniques to problems in the physiology of reproduction. One of these was concerned with the nature of afferent nerve fibre discharges from lactating mammary glands (A. L. R. Findlay); the others described work on the mechanism of feedback action of ovarian hormones (D. W. Lincoln; B. A. Cross and I. A. Silver).

The fourth session took the form of a symposium on the growth and function of the corpus luteum in mammals. The chairman, Dr. R. O. Greep, opened with a synopsis of earlier work on luteal function in the rat and rabbit. In the papers which followed, the emphasis lay in distinguishing between the growth of the corpus luteum and the biosynthesis and release of luteal progesterone in the guinea-pig (R. B. Heap, J. S. Perry and I. W. Rowlands), and in the interactions between the hypophysis and the uterus in controlling these processes in the sheep, sow and cow (R. Denamur, J. Martinet and R. V. Short; F. du Mesnil du Buisson; W. Hansel). Further evidence of the local effect of the uterus on the ovary was given for the sow, and a similar phenomenon was demonstrated by R. Moor and L. E. Rowson in the sheep by the surgical transfer of embryos to isolated segments of the uterus. The fact that one ovary may behave as though the animal were pregnant, while the other ovary behaves as though it were not, conflicts with the generally accepted picture of the hormonal relation between ovary and uterus, and is as yet unexplained. Work on the pituitary hormones responsible for maintaining the corpus luteum and stimulating the synthesis of luteal progesterone suggests that in the cow and the sow the main luteotrophin is LH (luteinizing hormone), whereas in the sheep it appears that the major factor is prolactin. These papers were discussed by R. Deanesly and B. T. Donovan in the light of their own work on the guinea-pig and ferret.

The fifth session opened with six papers on various aspects of reproduction in the male; it comprised work on the effect of nutrition on androgenic function in calves (T. Mann and colleagues), the preservation of human spermatozoa (M. Freund; D. Richardson), the control of fertility with drugs (B. N. Hemsworth and H. Jackson), and the effect of ageing of spermatozoa on fertilization and prenatal development (J. M. Tesh and T. D. Glover). By way of further variety, sperm dimorphism in a copepod was described by B. L. Gupta. Later papers, on reproductive function in the female, dealt with the gonadotrophin control of ovulation in several species, including human (M. E. Mitchell; H. H. Cole and R. B. Snook; M. Taymor; J. P. Bennett *et al.*).

A symposium on factors controlling the duration of pregnancy opened with a number of papers dealing with myometrial activity and the onset of parturition (B. M. Schofield; A. I. Csapo and T. Kerenyi; A. Riitta Fuchs; G. Wagner; W. R. Ward), and subsequent speakers described the influence of genotype, the immunological status of the fœtus, and a cold environment on the duration of pregnancy (M. W. H. Bishop; D. James; S. A. Barnett and M. J. Little). Attention was drawn to the distinction between animals in which the placenta produces progesterone, as in the human, and those in which it does not, as in the rabbit. It has been shown that strong uterine activity can be present without parturition, or without the maternal behaviour associated with it, in rats with progesterone implants in the hypothalamus.

A new surgical technique for the removal of the pituitary gland in the foetal lamb was described (G. C. Liggins and L. Holm), and this procedure was found to prolong pregnancy, an effect apparently mediated through the foetal adrenal gland. The chairman, Dr. A. McLaren, presented a paper on behalf of A. Psychoyos *et al.*, who have studied the relations between uterus and ovary in rats in which two sets of embryos were induced to implant asynchronously, so that the uterus was occupied by foetuses of different ages.

The final session was devoted to papers on problems in human reproduction and its control, including a morphological study of the utero-tubal junction (I. Rocker), the effect of oestrogens on the ovary (A. Netter), an analysis of fertility in married women (M. Barton), and the successful demonstration of the use of clomiphene to produce live spermatozoa in a case of Klinefelter syndrome (G. L. Foss). Work in Edinburgh has shown that chromosomal anomalies may be a major factor in unsuccessful pregnancies, and there is some evidence that the incidence increases in women over 35 years of age (M. G. Kerr).

OBITUARIES

D. D. Kosambi

THE death of Professor D. D. Kosambi on June 29, 1966, at the age of fifty-nine removed a unique figure, not only from India but from all society.

Kosambi had a most unusual and comprehensive education, partly in the United States, at Harvard, where his father taught Indic studies. He acquired early an interest in mathematics, which was his main contribution to science, particularly in the field of statistics and stochastic theory. This put him in the front rank of practical mathematicians and his interest was then transferred to theoretical and nuclear physics and he worked on fundamental research at the Tata Institute in Bombay under the general direction of the late Homi Bhabha.

I am not qualified to comment on his mathematical work, especially as much of it is concerned with number theory and calculus of variation; but I had a great deal to do with him as a man of quite exceptional intelligence and charm, particularly in the work concerned with the Indian peace movement, and I learned something of his wide scope of interests. Although trained in the United States, he remained from the very beginning mainly concerned with Indian problems, including Indian economics, history and archaeology. It was a pleasure to travel with him in his own country because, for Kosambi, history was not only in the past but also in the present.

In the extremely unsatisfactory records of Indian history which he has denounced in his books, he finds the preservations of beliefs and customs in many tribes and castes. He finds, for example, not only the places of worship but also actual names, such as that of the goddess Lumbini presiding over the birth of the Buddha, which have been preserved practically unchanged for 1,500 years. I witnessed one of these survivals myself outside the National Chemical Laboratory near Poona. It was a newly established shrine with a crude figure smeared with red paint and an attendant ascetic who, for a consideration, would offer up a prayer so that the new arrival into the laboratory could be assured of a good post.

Kosambi's interests stretched further than the geography of India. I accompanied him to the National Museum of Denmark in Copenhagen and he was able to tell the curator precisely what bones he would find at the bottom of a well because the Bronze Age Danes had the same horse sacrifice as the ancient Aryans of India.

Wherever he went he was able to trace out the early trade routes still in use in the age of steam and motor cars, and often transporting the same goods, including pots made with the slow and fast wheel, that had already been made in the Indus civilization in the second millennium B.C. For this he had also to perfect his knowledge of Indian languages and poetry. His father knew the whole of the 80,000 lines of the *Mahābhārata* by heart, and I remember Kosambi taking me to the Institute in Poona where a number of aged Indian scholars and their younger disciples were occupied in providing a comparative edition of that poem from numerous manuscripts on palm leaves and other fragile bases, reckoning that they had done a good day's work when they had completed one line!

Kosambi introduced a new method into historical scholarship, essentially by application of modern mathematics. Indians were not themselves historians: they left few documents and never gave dates. One thing the Indians of all periods did leave behind, however, were hoards of coins. These carry inscriptions which list kings or date markings, but they had been in circulation before the hoard was buried and had suffered varying degrees of wear before burying. By statistical study of the weights of the coins, Kosambi was able to establish the amount of time that had elapsed while they were in circulation and so set them in order to give some idea of their respective ages. In this way he was able to date these coins, known as punch-marked coins, weighed pieces of silver of carefully standardized weight marked with various devices which connected them with a definite king, sometimes many with a single king such as the great Asoka of the Maurya dynasty. The persistence of a coin is one of the most remarkable of human characteristics. In his book, *The Culture and Civilisation of Ancient India in Historical Outline*, Kosambi shows a picture (No. 62) of a coin of a Greek king, Menander, in North India, 180–160 B.C., which he found in 1940 circulating in an open air market in Poona as an equivalent of half a rupee.

His great contributions to historical science have been his two books *Introduction to the Study of Indian History* (Popular Book Depot, Bombay, 1956) and *The Culture and Civilisation of Ancient India in Historical Outline* (Routledge and Kegan Paul, London, 1965). These provide a history of an entirely different character to anything seen before. As he himself says in his latter book:

> "But what is history? If history means only the succession of outstanding megalomaniac names and imposing battles, Indian history would be difficult to write. If, however, it is more important to know whether a given people had the plough or not than to know the name of their king, then India has a history. For this work I shall adopt the following definition: *History is the presentation in chronological order of successive changes in the means and relations of production.* This definition has the advantage that history can be written as distinct from a series of historical episodes."

In his second book, Kosambi certainly bears out his definition. He shows a picture of a two-bullock plough of the same characteristic type with vertical handle and curved yoke-pole, taken from a relief of the Bodhisattva's First Meditation in the Buddhist caves at Junnar, as in use in A.D. 200 and still in use to the present day. They are, for all practical purposes, identical.

A great deal of Kosambi's book is taken up with the description of classical Indian political science. The *Arthasāstra* is a complete and almost Machiavellian description of how the great Indian state of Magadha (300–184 B.C.) was ruled and how the institutions of the complete police state could be adapted to the tenets of the purest Buddhism. He shows that the positive task of the Mauryan State consisted of opening up the territory of the Ganges Valley, including Bengal and even Assam, by clearing the tropical forests and assimilating, through institutions of Hindic religion, the local populations.

All this may seem very far away and long ago, but to Kosambi it was all in the present as well, illuminating the current difficulties of Indian agriculture and industry.

> "When gunpowder had blown Arguna's bow and later feudalism off the map, the Indian intellectual still turned instinctively to the (Bhagavad-) Gitā to find some way of coping with patriotic needs in the new world of banks and shares, railroads, steamships, electricity, factories, and mills. . . . The Gitā is honoured oftener than read, and understood far less than it is recited. After such mixed ideas are displaced by clear-cut thinking based on a firm grasp of material reality, the work may still furnish some aesthetic pleasure for its power of expression and peculiar beauty."

J. D. BERNAL

Continued from previous page

Observations were reported on the use of an intrauterine device in the rhesus monkey by J. H. Marston *et al.*; and further papers described the effect of oral contraceptives and intrauterine contraceptive devices on endometrial blood vessels and vaginal smears (E. Grant; M. Jackson and R. Linn).

Abstracts of the papers presented at the annual meeting will be published in the October issue of the *Journal of Reproduction and Fertility*, the official organ of the Society.

"LIVING FOSSILS" IN WESTERN ATLANTIC PLANKTON

By DR. DAVID WALL and BARRIE DALE
Woods Hole Oceanographic Institution, Woods Hole, Massachusetts

FOSSIL microplankton are a large group of ancient marine protista of planktonic origin that includes hystrichospheres and fossil dinoflagellates the shells of which are composed of organic rather than mineral material. They are used together with pollen and spores to date, correlate and interpret the palaeoecology of Mesozoic and Tertiary strata. Until recently, the existence of identical organisms in modern plankton was uncertain: hystrichospheres, for example, were thought to be extinct, while the youngest known fossil dinoflagellates (Miocene) were unlike living genera in critical details. Then morphological studies[1,2] of a few types of resting spores produced endogenously by common living thecate dinoflagellates quickly revealed that these spores were identical with several hystrichosphere and fossil dinoflagellate species known to occur in marine late-Tertiary and Quaternary sediments. Moreover, one such "living fossil" known as *Hystrichosphaera bentori* Rossignol (Fig. 1) was induced to excyst under laboratory conditions in single-cell culture experiments[2] to release a flagellated thecate motile stage of *Gonyaulax digitale* (Pouchet) Kofoid.

New discoveries resulting from improved extraction techniques and regular sampling of local Atlantic plankton at Woods Hole for more than 8 months have shown that many other hystrichospheres and similar dinoflagellate resting spores occur persistently in present-day oceans. More than forty types of dinoflagellate resting spores with diagnostic excystment apertures (archeopyles) have been isolated since February 1965; these include *Hystrichosphaera furcata* (Ehr.) Wetzel, *H. bulloidea* Defl. and Cooks, *H. bentori* Ross, *H. mirabilis* Ross (Fig. 2), *Nematosphaeropsis balcombiana* Defl. and Cooks (Fig. 3), *Baltisphaeridium machaerophorum* Defl. and Cooks, *B. centrocarpum* (Defl. and Cooks) Gerlach (Fig. 4), and *B. israelianum* Ross (using fossil nomenclature) together with several new species which have not been described formally, but are known to occur in the marine Pleistocene of the Caribbean Sea. Living hystrichospheres were collected from two sources, namely, the sea water and the sea floor surface layer. Those obtained directly from plankton were collected with a fine meshed (35μ) net; the remainder were isolated from humus on the sea floor or from the floors of large settling tanks where there was less turbulence. In each case selective concentration of the resting spores relative to other plankton was essential and accomplished by repeated sieving, sometimes with interposed ultrasonic vibration treatment, until only a clean 35–75μ fraction remained. An exceptionally rich sea-water sample rarely had more than thirty resting spores per litre and the most common type of hystrichosphere (*H. bentori*) seldom exceeded five cells per litre, but numerous individuals were obtained by using large volume samples of 100 l.

The resting spores of dinoflagellates recovered from local plankton at Woods Hole could be divided into four groups according to whether their excystment apertures or archeopyles were precingular, intercalary, cingular (hemispherical) or polar.

(1) Resting spores with precingular archeopyles included the "living fossil" species of *Hystrichosphaera*, *Nematosphaeropsis* and *Baltisphaeridium* already listed as common in local waters. In almost all instances the archeopyles represented the loss of a single plate-area (3″) from the dorsal surface, but rarely the opening was compound and four or five precingular plate-areas were missing, as in the cyst of *Gonyaulax polyedra* Stein[1].

The parental dinoflagellates of spores with precingular archeopyles belonged to *Gonyaulax* and *Protoceratium*. Two spores with simple archeopyles (*Hystrichosphaera bentori, H. bulloidea*) were united with their thecate stages (*Gonyaulax digitale, G. scrippsae*) in culture experiments, while seven other species of *Hystrichosphaera* have gonyaulacid parentage according to their tabulation, which was always 3–4′, 0*a*, 6″, 6*g*, 5–6‴, 1*p*, 1⁗. The spore of *Gonyaulax polyedra* was identified by its compound archeopyle and distal spinules[1] and was comparable with the common Quaternary fossil species *Baltisphaeridium machaerophorum*. Only one species of *Protoceratium*, *P. reticulatum*, is known to form spores with a precingular archeopyle[1]; these spores are similar to the Quaternary fossil *Baltisphaeridium centrocarpum* in most respects.

(2) Resting spores with intercalary archeopyles included more than twenty-five morphologically distinct categories. They were identical with fossils known to occur in Caribbean and Mediterranean Quaternary sediments in some instances and comparable with older species belonging to the fossil genera *Cleistroeisphaeridia* and *Deflandrea* in general. The archeopyles of these modern spores were basically hexagonal in shape but had variable height: width ratios (1 : 1 to 1 : 2·3) and sometimes a tendency towards asymmetry. Observations of cysts within thecae, dispersed spores and thecae released from cysts under single-cell culture experiments confirmed that the archeopyle was homologous with a dorsal intercalary plate (usually 2*a*, rarely 1*a*) and seldom compound. The position of the archeopyle was commonly subapical and dorsal, but in some instances (varieties of *P. oblongum*) the opening truncated the apex of the resting spore. In overall shape, the resting spores varied from subspherical to rhomboidal (peridinoid) to biconvex with polar compression. The majority were smooth-walled, but two types at least were spinose, including the spore of *Peridinium claudicans* Paulsen. All were deeply coloured but they varied from shades of brown to olive-green.

The parental dinoflagellates identified with these spores were species of *Peridinium* belonging to the subgenus *Orthoperidinium*, including *Peridinium oblongum* (Aurivillius) Cleve (Figs. 5 and 6), *P. claudicans* Paulsen, *P. leonis* Pavillard, *P. conicoides* Paulsen, *P. excentricum* Paulsen and *P. monospinum* Paulsen. Numerous other spores with intercalary archeopyles were found only in the dispersed condition, but their characteristic colours and often rhomboidal shapes were strongly indicative of peridinioid parentage.

(3) Two types of resting spores possessed cingular archeopyles consisting of an equatorial suture circumscribing the test apart from a small area of its ventral surface. Their natural affinities or any details of their tabulation remain unknown, but their archeopyles were basically similar to those seen in the Quaternary fossil species *Hystrichosphaeridium zoharyi* Ross.

(4) Apical excystment apertures were seen in two problematical forms. First, they occurred in certain mineralized dinoflagellate cysts (Family Calciodinellidae) which were similar to organisms first described by Gocht[3] from the Neocomian of Germany and Deflandre[4] from the Tertiary of Algeria and France. In single-cell culture experiments this circular aperture was observed to function as an excystment opening when a gymnodinioid body which quickly divided into two daughter cells was released. Secondly, empty shells of *Hexasterias* (*Polyasterias*)

Fig. 5. *Peridinium oblongum* (Aur.) Cleve (× 365). Theca enclosing a resting spore.
Fig. 6. Empty cyst of *P. oblongum* (Aur.) Cleve, showing the intercalary archeopyle (× 335).
All specimens illustrated from plankton at Woods Hole.

problematica Cleve frequently possess circular apical apertures. Dinoflagellate affinities have been suggested for this organism[5], but its parental species was not named. The striated, open hollow tubular processes make it particularly interesting as a possible surviving member of the "Tubiferum" microplankton group.

In many instances the resting spores of modern thecate dinoflagellates are morphologically distinctive (for example, *Hystrichosphaera bentori*), and identifiable in the dispersed state in which they are commonly found. Once the parental and thecate phases have been correlated by natural association or in culture experiments, the geological history of the species may be traced with the greatest precision. In general, observation of these modern resting spores supports the contention held by most micropalaeontologists that it is the most precisely defined fossil microplankton species that correspond most closely with natural groupings the members of which had mutual parents. Only a few cases are at present known where identical cysts are produced by parental dinoflagellates with different tabulations. These concern closely related neritic species or varieties of the "Oceanicum"-group of *Peridinium* (*P. claudicans*, *P. oblongum*) the present taxonomic status itself of which is open to revision.

Investigations of modern cysts clearly point to the value of the archeopyle as a criterion useful in tracing the phylogeny of dinoflagellates and in formulating diagnoses of fossil genera. They confirm by reference to more than forty different living morphological categories ("species") that the archeopyle is a fundamental characteristic of marine dinoflagellate resting spores the formation and function of which are defined precisely by genetic control. Living resting spores develop an incipient archeopylar suture before dispersion and long before their dehiscence. Fossil resting spores bear witness to the evolutionary stability of this structure since Jurassic times.

Moreover, the locus of the archeopyle is constant within narrow limits for resting spores produced by species of any modern genus according to existing information; it is precingular in *Gonyaulax* and *Protoceratium* and intercalary in *Peridinium*. Modern genera producing cysts with similar archeopyles (*Gonyaulax* and *Protoceratium*) are apparently closely related; the tabulation of *P. reticulatum* is very similar to that of *Gonyaulax*.

At present the systems of classification applied to thecate living phases and fossil resting spores are independent of each other although both rely on skeletal morphology to a large extent. Now that more comprehensive knowledge of the morphology of modern resting spores has been compiled, several recommendations based on biological studies may be presented in an attempt to ensure that the two systems of classification are compatible. A special effort should be made to determine the nature of the archeopyle before any fossil species is described. All fossil genera should be diagnosed to include mention of their archeopylar structure and species with different kinds of archeopyles should not be placed in the same fossil genus. Fossil genera the archeopyles of which originate from different series of thecal plates (precingular, intercalary) should not be placed in the same family.

The biological function and ecology of living hystrichospheres and other resting spores are of interest to the palaeontologist but are poorly understood at present. The functions of marine dinoflagellate resting spores include protection of the protoplast against conditions adverse towards the thecate stage, propagation of new plankton crops and migration of the species by spore dispersal. However, the genetic significance of this phase is unknown. The role of environmental stimuli in inducing cyst formation also is poorly understood. Resting spore formation in certain fresh-water dinoflagellates (*Glenodinium uliginosum* Schilling) has been correlated with a rapid fall in temperature prolonged over several months[7], but in marine species spore formation can occur before there is any marked decline in temperature and while the thecate stage is abundant and growth conditions appear optimal. Single-cell culture experiments have shown that temperature fluctuations can be effective in inducing excystment. The resting spore of *Gonyaulax digitale* will release its motile stage at 16°–25° C after isolation from colder water, but will not excyst under the same conditions immediately following its formation indicating that a resting period is required. Different types of marine *Peridinium* resting spores have been excysted at 6°–7° C and at 23° C, indicating that this process in different species may occur in either cold or warm water conditions. Future investigations may clarify understanding of these processes and provide ecological information concerning the seasonal and geographic distribution of hystrichospheres in the oceans.

This work was supported by a grant from the National Science Foundation and a contract with the Office of Naval Research.

APPARENT CORRELATION BETWEEN THE LUNAR ECLIPSE BRIGHTNESS AND THE SOLAR WIND

By PROF. SATOSHI MATSUSHIMA

Department of Physics and Astronomy, University of Iowa, Iowa City, Iowa

IN recent years there have been numerous reports of observations of luminescent brightening of the Moon assumed to be caused by bombardment of the solar corpuscular radiation[1]. Among them, unusual enhancements shown in direct photographs of the Moon taken by Kopal and Rackham[2] appear to offer the most convincing evidence for the assumed phenomenon. However, the weakness of the luminescent light compared with the sunlight reflected by the lunar surface makes observation of this phenomenon very difficult. Kopal and Rackham have found that the energy required to produce the excess of light observed in their photographs is a few orders of magnitude greater than the amount of interplanetary plasma flux so far observed from space probes[3]. The brightness of the Moon decreases by a factor of 10^3–10^5 at the time of a lunar eclipse, so that, if the interplanetary or magnetospheric plasma were to bombard the Moon in the Earth's shadow, the luminescent brightening would be readily detected during a lunar eclipse. In fact, in some of the past eclipses, the brightness of the Moon has been 15 per cent or so greater than that predicted from theoretical calculations[4]. Link[5] was the first to suggest that luminescent emission caused by enhanced radiation from the solar corona was responsible for this increase in brightness. This point prompted me to investigate, on the basis of recent results of space experiments, whether there is any correlation between the brightness of the Moon during an eclipse and the interplanetary plasma flux.

A positive-ion spectrometer flown on *Mariner* II provided Snyder, Neugebauer and Rao[6] with about 40,000 plasma spectra for the course of the entire flight to Venus. From these measurements, they found a remarkable correlation between the plasma velocity and the planetary index of geomagnetic disturbances. From the least square fit of the plots of the observed velocity, V_p, against the daily mean planetary index, ΣK_p, they derived a linear equation

$$V_p\,(\mathrm{km/sec}) = (8{\cdot}44 \pm 0{\cdot}74)\ \Sigma K_p + (330 \pm 17) \quad (1)$$

If it is assumed that the relation is correct, equation (1) can be used to determine the solar wind velocity at any time during the past 30 years for which 3 h range as well as daily mean values of K_p are available. An extrapolation of this equation yields a range of the plasma velocities from 330 km/sec for $K_p = 0$ to 940 km/sec for $K_p = 9$. Another important finding made in this experiment was that there was no strong correlation between the plasma velocity and "over-all" solar activity as determined by sunspot number and 10·7 cm radiation.

In order to minimize the various corrections necessary when combining observations of different eclipses, the data selected for the present analysis consist of a series of three-colour photometric observations (centred near λ = 4700, 5300, and 6200 Å) of eighteen eclipses between 1932 and 1957 made by Danjon, Dubois and Rougier[7]. All the measurements were taken at a point 10 min of arc inside the umbra-limb with the same "cat-eye" or double-image photometer which was specially designed for the observation of lunar eclipses by Danjon[7]. Thus, if we assume that the distribution of refracted light in the Earth's shadow is radially symmetric, these data can be combined for direct comparisons.

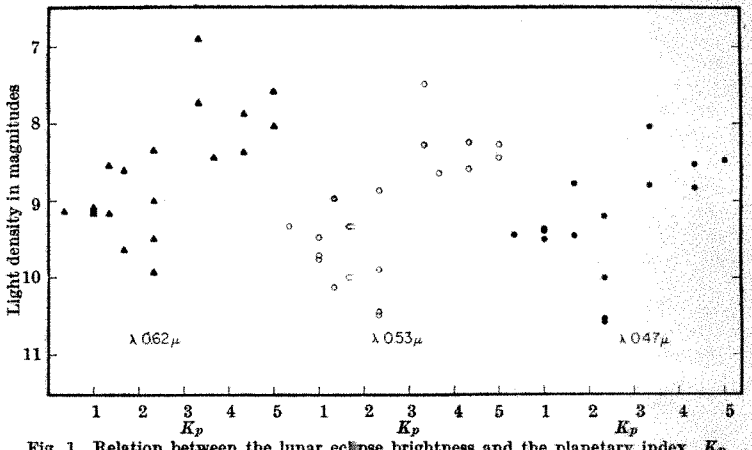

Fig. 1. Relation between the lunar eclipse brightness and the planetary index, K_p. The ordinate unit multiplied by −0·4 gives the logarithmic ratio of the brightness of an eclipsed Moon to that of the full Moon.

In Fig. 1 the observed brightness is plotted against the 3 h mean K_p at the time of each eclipse. The light density is defined by the ratio of the brightness of an eclipsed Moon to that of a full Moon, and is given in terms of the stellar magnitude scale. (The unit of stellar magnitude is equal to the logarithmic unit with base 2·512, or it corresponds to 0·4 times the logarithmic unit with base 10.) Although the range of scatters is rather large, it can be seen that there is a monotonous increase of light density with increasing K_p. Furthermore, similar plots made with 24 h mean values of K_p showing the same correlation can be seen in Fig. 1. It should be noted that theoretical calculations indicate that a point 10 min inside the umbra-limb is illuminated by light rays passing through the atmospheric region higher than about 10 km (ref. 8), which is well above the cloud region. The random fluctuations of the observed points seem to result partly from the differences in albedo of the points of observations and partly from the variations of extinction in the upper atmosphere. In view of the precision that can be expected, however, the random errors in Fig. 1 do not seem to be too serious.

Many years ago, Danjon[9] suggested that the brightness of the eclipsed Moon depended on the sunspot cycle. Using his own scheme of calibration, based mostly on the colour of an eclipsed Moon, Danjon estimated the relative brightnesses of a number of visually observed eclipses

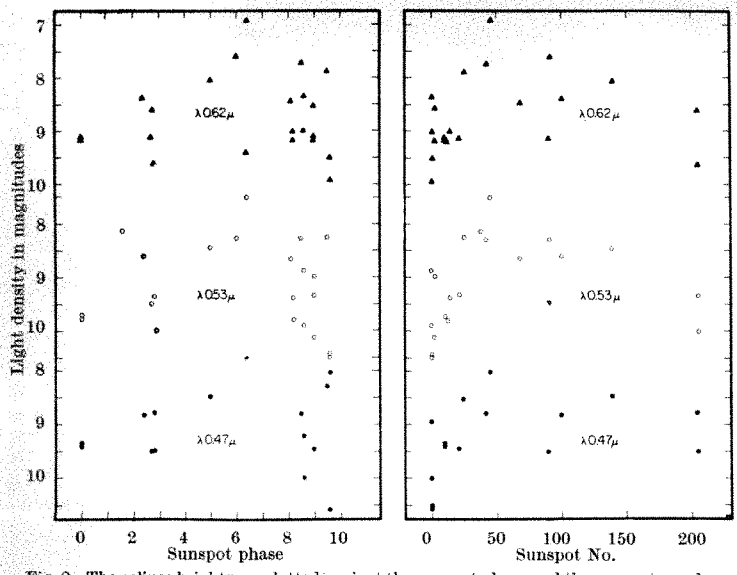

Fig. 2. The eclipse brightness plotted against the sunspot phase and the sunspot number.

between 1823 and 1920. He concluded that the brightness increases monotonously from a time of sunspot minimum until it reaches the maximum brightness just before the next sunspot minimum and then drops sharply to the minimum brightness when the sunspot activity begins a new cycle. This point can be examined for the same set of data used in the present analysis in Fig. 2, where the observed density is plotted against both the phase of sunspot cycle and the actual number of sunspots observed on the date of each eclipse. Contrary to Danjon's findings, no obvious correlation can be seen in either diagram. This appears to be consistent with the experiment by Snyder *et al.*, in which no clear relationship was detected between the plasma velocity and the sunspot number.

While it is now believed that the Earth's magnetosphere extends to the distance of the Moon's orbit, experimental knowledge of the kinetic behaviour of the plasma flow near the geomagnetic tail region is still incomplete and theoretical predictions are confusing[10]. Neglecting this uncertainty, it can tentatively be suggested that the monotonous increase in light density showing in Fig. 1 results from the fluorescent emission caused by the bombardment of interplanetary plasma. If this is so, the question of the energy balance of the assumed process must be examined quantitatively.

For convenience of calculation, the observed light density is converted to the absolute unit of radiant energy flux for 1 Å width, and is plotted against the plasma velocity derived from equation (1). All the straight lines are drawn through the points with the logarithmic gradient of 4, indicating that the emittent energy is proportional to the fourth power of the plasma velocity. Because the bombarding plasma flux is proportional to the cubic power of the velocity, we can accept the proportionality to the fourth power if we assume that either the proton density or the luminescence efficiency increases linearly with the velocity. On the other hand, if we take the former and assume that the luminescent flux is comparable with the reflected light, we obtain from the straight lines

$$\log E_\lambda = 4 \log V_p + \log N_0 + \log Q_\lambda/\Delta_\lambda + \text{constant} \quad (2)$$

where N_0 is the proton density per unit velocity, and Q_λ and Δ_λ are the efficiency coefficient and the half width of the luminescent spectrum, respectively. If we take the efficiency factor of 1·0 and assume the half-width of the luminescent spectrum to be of the order of 1000 Å, we find for the red region, N_p = 20/cm³ for V_p = 330 km/sec (K_p = 0), and N_p = 35/cm³ for V_p = 600 km/sec (K_p = 4). The blue and green regions give slightly higher densities. In reality, the luminescent emission should be a certain fraction of E_λ in equation (2), and the proton densities will be correspondingly lower. For example, if we assume the luminescence is about 10 per cent of the total emission, the corresponding proton density becomes a few per cubic centimetre which agrees with the value generally assumed for the steady flow of the solar wind.

Although this calculation is approximate, it is sufficient to show that the correlation found between the brightness of a lunar eclipse and the interplanetary K_p index can be interpreted as arising from the effect of lunar luminescence. A more detailed investigation of this interpretation, together with similar analysis for other recent observations of lunar eclipse[11], is now in progress.

I thank Prof. J. A. Van Allen and Prof. T. Obayashi for their stimulating discussions. I also thank Prof. F. Link for directing my attention to the possibility of luminescence on the brightness of lunar eclipses. This work was supported in part by two grants from the National Science Foundation.

SIMULATION OF A PERCEPTUAL PROBLEM-SOLVING SKILL

By Dr. A. ELITHORN, J. R. JAGOE and Dr. D. N. LEE*
The Institute of Neurology, the Institute of Computer Science and the Royal Free Hospital, London

In the physical sciences, the use of large digital computers in the development of models is now a well established technique. In psychology and the social sciences the technique, though not without its successes, has been less well accepted. One difficulty facing the behavioural scientist is that the problems in which he is interested involve a large number of variables which can rarely be systematically controlled.

A previous paper[1] reported the development of computer designed psychological test material in which the variables determining difficulty could be systematically varied and which was suitable for the study of perceptual skills and certain aspects of human problem-solving mechanisms. Because this material is being increasingly used both in the clinical field and as a research instrument[2-4] it seemed worthwhile to develop computer model-building techniques to test hypotheses about the mechanisms different subjects use in solving this type of problem. Fig. 1 shows a sample of the problems used.

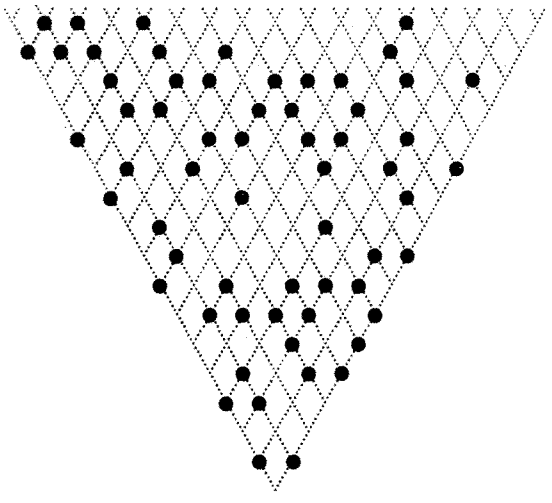

Fig. 1. An example of a difficult maze.

The display consists of a lattice background on which is superimposed a number of target dots. The subject is required to find a pathway through the lattice which obeys the following rules: it must start at the bottom vertex and end at the top row and it must lie wholly along the lattice lines; it must be unidirectional in a general upward sense; it must pass through the greatest possible number of target dots. This task may be presented in one of two forms. Either the subject may be told the maximum possible score or this information can be withheld. These two versions will be referred to as *A* and *B* respectively. Under condition *A* the subject has to discover a pathway with a specified score and is left in no doubt as to whether or not he has found a solution. Under condition *B* he has to decide himself whether further effort will produce a better solution.

A number of studies suggest that success with these problems is a function of fairly fundamental perceptual skills which correlate with intelligent adaptive behaviour. As might be expected, these skills are sensitive to brain damage[2] and the type of breakdown is a function of the site of the lesion[5]. As with many perceptual and spatial skills, there are also differences in performance related to sex, personality variables and age[4,6].

Because the format of the maze is well defined and amenable to relatively simple mathematical description, structural properties which correlate with the difficulty of individual items may be defined as numerical parameters[1]. These can be systematically varied and the effects of doing so related to the relative difficulty of different patterns for defined groups of subjects. The models described here are based on a detailed analysis of data from such a study carried out with two groups of normal subjects: 144 Royal Air Force male recruits matched with 144 female recruits for age, intelligence and education. Each subject attempted every one of a set of seventy-two mazes, each with a sixteen-rowed lattice and sixty-one target dots the arrangement of which had been specified by a computer programme. Each test set was divided into two sets of thirty-six items, one presented under condition *A* (with the solution number given) and the other under condition *B* (without the solution number). Half the subjects took version *A* followed by version *B*, the other half version *B* followed by version *A*. Practice effects were balanced by means of a randomized Latin Square design and the subjects were allowed 30 sec for each item. Thus it was possible to derive for men and women and for each condition an estimate of the difficulty of each item which was unbiased with regard to practice and fatigue effects. Further details of this experiment, henceforth referred to as Experiment *D*, have been given elsewhere[7,8]. In the present article we relate these estimates of difficulty to the successes and failures of two models in the form of computer programmes which simulate limited but contrasting aspects of the human maze solving process. This maze solving process is likely to incorporate a variety of related strategies. Of the two models described, one defines a systematic search for valid links between groups of target dots and the second a total encoding of the dot relationships.

With the present size of pattern, an exhaustive sequential search would mean that in the no-information condition subjects would have to examine 65,536 solution pathways. Such an approach would not only be time consuming but, for a human, difficult to carry out. How then do subjects go about solving the problem of linking together a maximum number of target dots? Subjectively most subjects say that they first scan the maze for areas with a high target dot density. Attempts are then made to relate these areas together. In other words, the subject makes an analysis of the groupings of target dots and the relationships between these groups in order to decide which dots can be linked to form a solution. Although ultimately defined by the lattice background, the permissibility of dot linkages might in the first instance be assessed on the basis of the angular relationships between groups.

However, some types of linkages will be more obvious than others; some dots may be perceived as linked when there is no valid path connecting them. Again some relationships, such as horizontal groupings, may appear more attractive than their problem-solving value warrants.

Grouping the target dots as runs (that is to say, into pathway segments containing target dots with no empty nodes) is a simple encoding strategy. It does not itself solve the maze but provides one possible basis for a whole

* Present address: Center for Cognitive Studies, Harvard University.

class of strategies. For example, a subject might scan the maze, pick out a large group of dots and use this as a focal point for a pathway. Alternatively he might try to link up runs of dots working systematically from the vertex to the top (or from the top down). In this case we may visualize the subject as starting at the vertex and making a series of decisions to fork left or right based on the configuration of dots in the rows immediately ahead. If this decision is made on the basis of a more or less complete knowledge of this configuration, then the number of rows ahead that the subject will be able to scan will be very limited. Clearly most subjects will not search only from below upwards, nor if they did would their decisions be taken only on the basis of complete knowledge of a limited area. 'Look ahead' is in fact likely to be complete for the immediate neighbourhood and to spread forward on an increasingly impressionistic basis.

Such assumptions, therefore, are simplified approximations from which subjects will depart to a greater or lesser extent. The results of Experiment *D*, however, suggested that scanning from below upwards is more common than scanning from above down and that the effective 'look ahead' of some subjects is quite short. Moreover, subjects tend to adhere to, or continue to the end of, a run in preference to breaking away to a new group, even though the latter gives a better score. There is also a preference for continuing in a straight line.

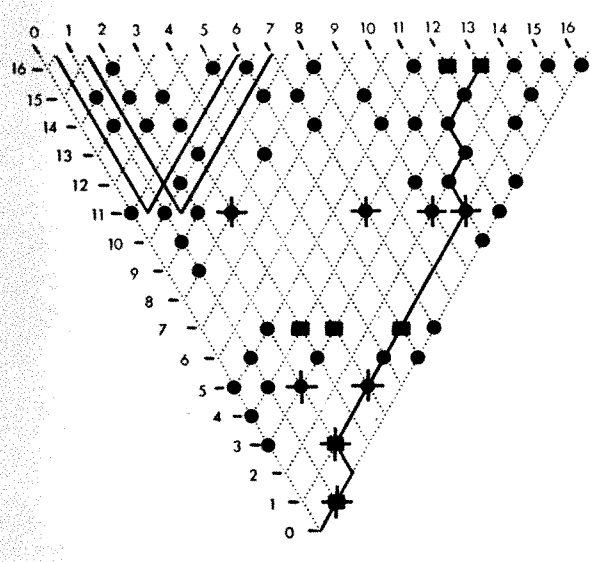

Fig. 2. This diagram illustrates (1) the first strategy, and (2) the opportunity cones used in the second strategy. (1) The target dots chosen by the strategy as base nodes are marked with a -●- and those chosen as top nodes with a box ■. The first two runs are in fact singletons (1,1), (3,2). From the second of these two base nodes three runs of three are accessible which end in three top nodes (7,3), (7,4), (7,6). All these are therefore used to generate a fresh set of base nodes. There are four of these, the two left-hand ones (11,3), (11,7) being singletons. The two right-hand ones (11,9), (11,10) belong to the same group and each generates two runs of 6. Since both can be reached only from the right of the three preceding top nodes (7,6), this is chosen from the preceding 3 runs. From here there is no preference for either of the two right-hand top nodes (16,12), (16,13) and the principle of "continuation" determines the choice of node (16,13). The final path chosen by the strategy is as marked in the diagram. (2) The two overlapping cones in the top left-hand corner define the opportunity cones based on the two apical nodes (12,1) (12,2) which in the second strategy (if the pathway had reached this point) would determine the decision taken at the node (11,1).

In the first strategy (Fig. 2) a maze solution is considered as a series of runs of dots, the direction of the pathway being from the vertex up. The end or top dot of a run will be referred to as a top node, the start or bottom as a base node. Conventionally, the vertex, which never contains a target dot, is defined as a top node; the pathway starts here and is constructed in steps. At each top node the next run of dots is chosen, which in turn terminates at the next top node of the pathway.

The procedure for choosing the next run of dots is as follows: the accessible parts of each row above a top node are scanned until a dot is found; all the accessible dots in this row are considered as possible base nodes for the next run. The next row above this is also scanned and accessible dots on this row are considered as base nodes if, and only if, they are not linked to any base node on the previous row. Clearly a base node is not always the lowest dot in a run; it is the lowest dot in a run which is accessible from a top node. Thus, from each top node except those which relate only to the top of the maze a set of base nodes can be found. The runs of dots starting on each of these base nodes are then determined, each run terminating on a next possible top node for the pathway. Of this set of next possible top nodes, the one with the maximum run of dots up to it is chosen. If there is no unique maximum, then the 'maximum' top nodes are considered in turn, and the above procedure applied to each of them. The maximum run available to each new top node is found and the next top node of the pathway is chosen on this basis. Target dots may of course act as both base and top nodes, either because they are singletons or because only the final dot in the run is accessible from the previous top node.

The general function of the strategy therefore is to start at the vertex, choose a maximum run and at the top dot of this run choose the next maximum run and so on. However, certain decisions must still be made. These affect the path taken within a group of equal runs which finish on a given top node, the path taken between a top node and the next base node, and the path when all the routes to the top are equally good. These decisions could have been selected randomly, but it seemed preferable to implement some additional hypotheses about maze-solving strategies. The first of these predicts that, other things being equal, subjects will continue in a straight line (continuation principle). If the strategy was indecisive about the very first decision, the right-hand path was chosen.

Using the patterns from Experiment *D*, this strategy was programmed and run on the University of London *Atlas* computer. Of the seventy-two items, the model failed to find a correct solution in twenty-two, and the pattern of success and failure was similar to that of the Royal Air Force subjects in that the model failed only three of the ten easiest items and passed only one of the ten most difficult. The rank correlation with success or failure was 0·38. The results are summarized in Fig. 3.

This simulation programme combines a minimal local encoding component with an elementary search procedure. Two important components are not considered at all. First, the strategy does not systematically take account of the effect of distant configurations on local decisions. Second, the strategy relates to a reduced transformation which ignores possible alternative paths through the open lattice between groupings of target dots.

The second simulation programme takes account of both these points. In this model the subject is seen as taking sequential binary decisions from the vertex to the top. At each decision point he is faced with a choice between two opportunity cones (Fig. 2); the relative attractiveness of these two cones is a function of the number of target dots each contains and the arrangement of these dots. Each target dot thus influences the decision process related to the vertex node of every opportunity cone. The problem, therefore, is to derive a function which represents for each node not the true value of its opportunity cone but the attractive force towards that node as perceived by the subject. A decision strategy can then start at the vertex of the pattern and at each bifurcation choose the most attractive node and so on up to the top. These derived values must be a function both of the pattern of the maze and of the group of people or the individual looking at the maze.

One approach makes an analogy between subjects solving the maze and current flowing in a resistance network. Subjects tend to take the path of maximum dots,

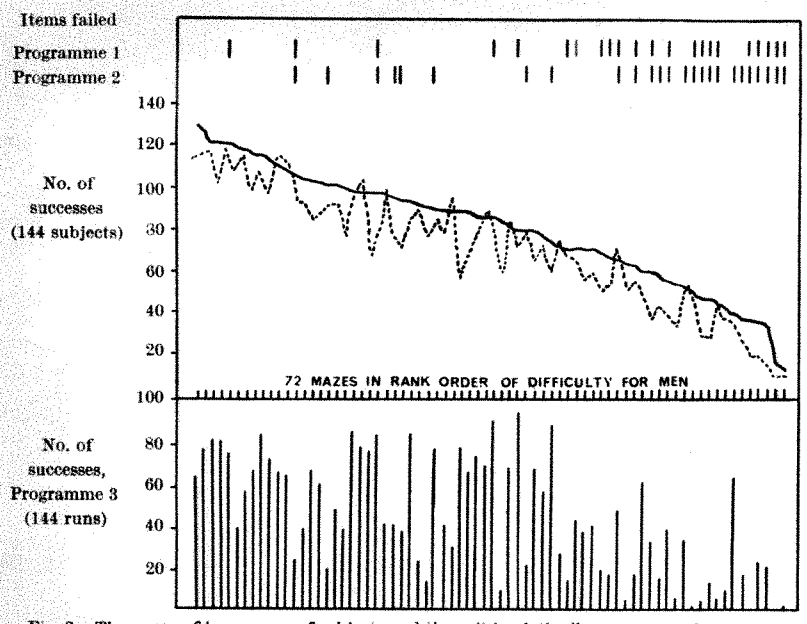

Fig. 3. The scores of two groups of subjects and three "simulation" programmes for 72 maze items. The central graph gives the number of successes for 144 male subjects (solid line) and the score for 144 female subjects (dotted line). The apparent greater variability of the female subjects reflects the fact that the items are arranged in rank order of difficulty for men. Above the graph the two rows of symbols indicate which items were failed by programmes 1 and 2. The histogram below the graph shows the number of passes achieved by programme 3 in 144 "attempts" at each item.

though not all of them succeed; current tends to take the path of least resistance, but not all of it does so. If, therefore, the maze is transformed into a resistance network in which the nodes with target dots have resistances of lower value than the nodes without target dots, and it is assumed that current can only flow along the pathways in the direction allowed to the subjects, it is possible to compute the value of the resistance from every node in the maze to the top. This value at any given node is a function of the total pattern of the cone with that node as vertex. If there are many target dots in the cone, then the value will generally be low: if these dots are arranged more in a vertical pattern than a horizontal one, and if there are dots close to the node, the value will be low again. In other words the value of the resistance from a node to the top reflects some of the perceptual components which are likely to attract a subject to that node. A similar analogy to games with strong perceptual components has been made by Shannon[9].

This model is again extremely simple and there are only two parameters to be determined. The first is the value of the two resistances. The second is a probability function determining the decision at each node. In the first instance the simplest cases were taken. The resistances were calculated on the basis that an empty node possessed unit resistance and a node with a target dot zero resistance. The decision function was always to go to the node of lowest resistance or if they were equal to the right-hand node. This programme solved forty-eight of the seventy-two items, the rank correlation with success or failure of the subjects being 0·41; the results again are presented in Fig. 3. In this form the programme gave only a single pathway. A third programme using the same resistance values was run using decision probabilities based on the arithmetical difference between the two resistance values determining each decision. These probabilities were calculated from a smoothed function derived from the decision behaviour of a subset of twelve men and twelve women in Experiment *D*. This programme was run 144 times for each maze to give a set of solutions which could be compared directly with the two sets derived from the groups of men and women. In this form and with this number of runs the programme failed to find a solution path in only two of the mazes (Fig. 3). The correlation between the performance of the programme and that of the subjects was significantly higher, being 0·60; higher correlations would almost certainly be obtained by manipulating the two parameters systematically.

One of the characteristics of the present test material which makes it particularly suitable for use with model building or simulation techniques is that there are usually a large number of different failure solutions and in general more than one correct solution. It is thus possible to assess the model in terms of the similarity of its performance to both the successes and the failures of the subjects. In the present instance we can usefully ask whether the model tended to make the same or a similar mistake on the mazes on which it failed. Because all solution paths have a common origin, a primary characteristic of an incorrect pathway is the point at which it first leaves or breaks away from a correct pathway. For the first two programmes Table 1 shows for these breakaway points the number of subjects who deviated from a correct solution at the same point as the simulation programmes and the number of subjects who at this point stayed with the correct solution pathway.

Table 1. PERCENTAGE OF SUBJECTS DEVIATING WITH STRATEGIES*

For mazes failed by:	Total (per cent)	Women *A* (per cent)	Women *B* (per cent)	Men *A* (per cent)	Men *B* (per cent)
Strategy 1 only	21·1	21·8	29·9	19·1	18·3
Strategy 2 only	22·1	18·2	23·5	19·9	22·5
Both strategies, same failure points	30·9	31·3	35·6	22·8	33·4
Both strategies, with different failure points:					
Strategy 1	21·6	19·5	26·5	18·0	22·4
Strategy 2	30·9	30·5	36·5	26·6	33·0

* The table gives the number of subjects deviating from a correct pathway at the node at which a strategy deviates, expressed as a percentage of the total number of subjects passing through the node. Under condition *A* the subject is told the solution number, under condition *B* he is not.

Finally, it is worth comparing the theoretical implications of the two types of model. In the first, specific types of behaviour are programmed to test whether or not they correspond to human maze solving skills. In the second, the relationships within the perceptual field are transformed to an analogue which allows the systematic variation of certain parameters. Although the first method is the most promising, the second can provide—and indeed has provided—useful insights into some of the mechanisms involved in this type of problem-solving behaviour.

The programmes described here were developed on the Institute of Computer Science Ferranti *Atlas* computer, and we thank Prof. R. A. Buckingham for his support and advice. We also thank Mr. Benedict Nixon for many helpful discussions. Dr. A. Elithorn and Dr. D. N. Lee were supported by a grant from the Medical Research Council, Mr. J. R. Jagoe by a grant from the Ministry of Health.

AN ELECTROKINEMATIC THEORY OF MUSCLE CONTRACTION*

By NEIL P. INGELS, JUN., and DR. NOËL P. THOMPSON

Palo Alto Medical Research Foundation, Palo Alto, California, and Stanford University, Stanford, California

THIS article proposes a theory of muscular contractile force development based on an electrostatic attraction of the solenoid-like structures formed by the actin and myosin filaments in striated muscles[1–5] (see Fig. 1). By assuming actin filament charge densities to be regulated by sarcoplasmic reticular calcium fluxes, we have theoretically determined that such microscopic solenoids can develop contractile forces very similar to those measured in living muscles. Our hypothesis differs from the mechano-chemical theories of H. E. Huxley and Hanson[6,7] and A. F. Huxley and Niedergerke[8,9] in that the myosin cross-bridges are not assumed to develop mechanically the contractile forces between the filaments. It differs from the electrostatic theory of Spencer and Worthington[10] in that excitation does not lead to momentary actin-site charge reversals with subsequent "jumps" of independent myosin filaments. It quite readily leads to the development of maximum tetanic force, predicts the nature of active-state tension development, and develops typical length-tension diagrams.

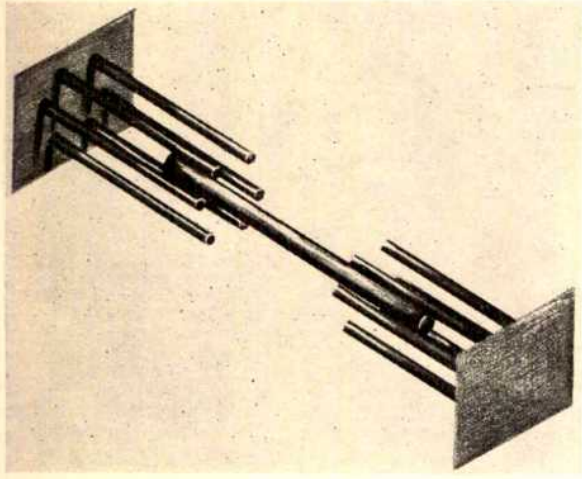

Fig. 1. The basic ordered structure formed by the actin and myosin filaments in striated muscles, a structure repeated more than 10^{14} times in each cubic centimetre of the muscle volume. Two groups of six *F*-actin filaments are shown, attached at one end to the *Z*-membranes to form a hexagonal array about a centrally located *L*-myosin filament.

The concept of charges bound to the internal filaments of both resting and active muscles is basic to this electrostatic theory. Since amino-acid analyses[11,12] and electrophoretic studies[13,14] indicate that the myosin molecule is negatively charged in nearly physiological solutions, and because the heavy meromyosin cross-bridges are known to bind firmly negatively ionized ATP[15,16], the myosin rods are considered as negative line charges in this hypothesis, as schematically depicted in Fig. 2. Although negative charges also bind to the *F*-actin filaments, primarily as ionized ADP[17–19], the recent work of Kobayasi[20] suggests that an equal number of evenly distributed positive charges bind to these filaments, which implies net charge neutrality of the actin filaments in resting muscle, also depicted in Fig. 2. Thus, no electrostatic contractile force is generated in the resting muscle owing to the net zero line charge on the actin filaments. The physical behaviour of the relaxed muscle fibre is determined solely by the viscous and elastic properties of the internal structures within the fibre[21–24].

If an electrostatic contractile force is to develop in the sarcomere during stimulation, however, the *F*-actin filaments must become positively charged. The four structures adjacent to the *Z*-membranes in Fig. 2 are assumed to play an important part here. These structures, known as the lateral cisternae of the sarcoplasmic reticulum, act as storehouses of divalent calcium cations in striated muscles[25–28]. When stimulated, they release their stored ions, which diffuse into the interfilamentary spaces, react with the filaments, and initiate the development of the contractile force[29–36]. When the excitation ceases, the cisternae actively accumulate once more those calcium ions just released[25–28,37–39]. Although the mechanism of this release and re-accumulation is not at present fully understood, it is clear that contraction and relaxation are controlled by the levels of free calcium ions in the sarcomere volume[34–36]. Concentrations of these ions greater than 10^{-7} M lead to muscular contraction; concentrations less than this cause relaxation[40–42].

Fig. 3 depicts a mechanism by which these calcium ions are postulated to cause the sarcomere to contract.

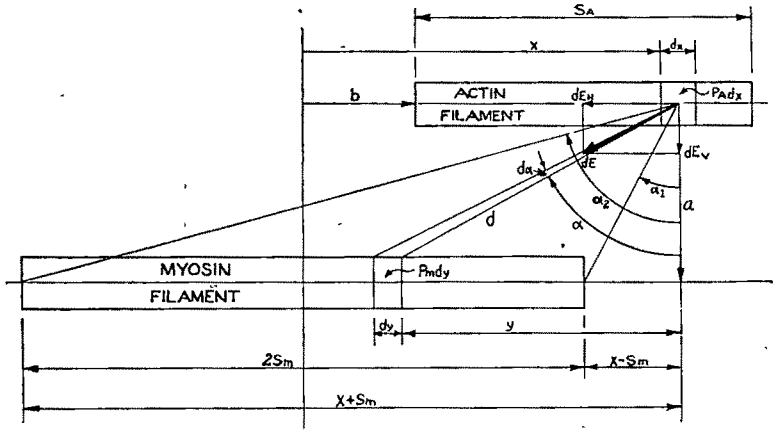

Fig. 4. Filament geometry for mathematical derivation of forces between actin and myosin rods.

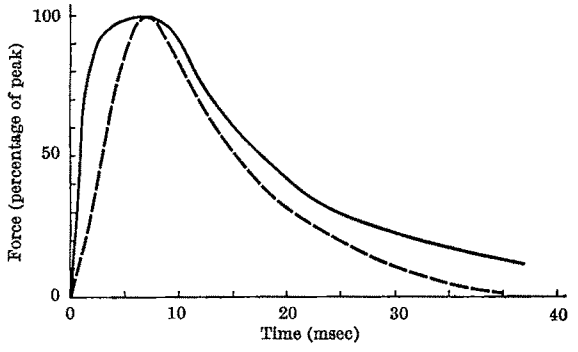

Fig. 5. Active state force development after single stimulus. ————, Experimental; — — — —, theoretical prediction by this hypothesis. Experimental curve scaled.

The muscle has just been stimulated, and the lateral cisternae have responded by releasing calcium ions into the inter-filamentary spaces*. Those ions released are assumed to react with sites on both the actin and myosin filaments in a concentration dependent fashion. Ions reacting with the actin filaments are postulated to induce a net positive charge on these filaments at their reactive sites. Because the calcium concentration is greater near the *Z*-membranes than at points distant from these structures, the actin filaments assume their greatest positive charge densities at points nearest the membranes, as depicted in the graph in Fig. 3. Reactions on the myosin filaments, which require the presence of myosin-bound ATP, are assumed to maintain the negative charge densities along these filaments as well as unlock the electrostatic bonds which form between the oppositely charged filaments during contraction. Thus, an electrostatic contractile force is developed in the sarcomere after stimulation. The positive charges on the *F*-actin filaments attract the negative charges on the *L*-myosin filaments and the muscle contracts.

When the stimulation is terminated, the sarcoplasmic reticulum actively returns those ions previously released to the lateral cisternae, which rapidly lowers the concentration of free ions in the sarcomere below the threshold value of 10^{-7} M. Because the net *F*-actin charge density is reduced to zero by this process, the muscle relaxes. Thus a complete cycle of contraction and relaxation is brought about by the release and reaccumulation of calcium ions by these reticular structures with the resulting modifications of charge densities which these ions bring about along the actin filaments.

The consideration so far represents a qualitative description of our electrokinematic theory. In order to investigate the interplay of these events in a quantitative sense, however, we must express the hypothesis in mathematical form. This derivation has been accomplished and is outlined in the following.

Assume that the myosin rod has a line density of P_m charges per metre (see Fig. 4). We desire to find the field intensity at x on the actin rod resulting from this line charge. The horizontal component of the electric field at this point is[43]

$$E_H = \frac{P_m}{4\pi\varepsilon a}\left(\cos\alpha_1 - \cos\alpha_2\right) \qquad (1)$$

where ε is the dielectric constant of the medium surrounding the rods and a is the distance between them.

Since the sarcomere volume (V) remains constant as the sarcomere length changes[44], we have

$$2\pi a^2(S_A + b) = V \qquad (2)$$

where S_A is the length of the actin filament, and b is half the width of the H zone. Expressing the cosine terms in equation (1) as functions of x and substituting the value of a found in equation (2) into the resulting equation yields:

$$E_H = \frac{P_m}{4\pi\varepsilon}\left[\frac{1}{\sqrt{(x-S_m)^2 + \frac{V}{2\pi(S_A+b)}}} - \frac{1}{\sqrt{(x+S_m)^2 + \frac{V}{2\pi(S_A+b)}}}\right] \qquad (3)$$

where S_m is half the length of the myosin filament.

If the actin filament has a positive line charge density $P_A(x,t)$, then the force tending to contract the sarcomere at any time (t) is

$$F = \int_b^{S_A+b} E_H P_A(x,t)\,dx \qquad (4)$$

where E_H is given in equation (3). (It should be noted that Debye–Hückel theory, with its many restrictive assumptions[45], is not used in this derivation. An attempt is made, however, to approximate the effects of double layer screening by reducing the filament line charge densities used in the computer solutions of equation (8).) If, however, this actin line density $P_A(x,t)$ is related to local calcium concentration $C(x,t)$ by

$$P_A(x,t) = K_1C(x,t) + K_2 \qquad (5)$$

then one must determine $C(x,t)$. This is the solution of the one-dimensional diffusion equation with reversible binding and irreversible first order reaction[46,47]. For purposes of analysis, the sarcomere is considered to be a cylinder with ends at $x = \pm(S_A + b)$. The initial and boundary conditions are then

*Although the case of *Z*-plane calcium release is analysed here, this is not a unique condition for force development in this hypothesis. Maximal isometric force is readily developed with calcium release from the *A–I* boundary, as in some types of striated muscles; however, this force is developed at a somewhat greater sarcomere length (about 2.6μ rather than 2.2μ).

$$\frac{\partial C(x,t)}{\partial x} = 0;\ x = 0, \forall\ t$$
$$C(x,t) = C_0;\ x = \pm\ (S_A + b), \forall\ t \qquad (6)$$
$$C(x,t) = f(x);\ \forall\ x,\ t = 0$$

A solution of the diffusion equation satisfying these constraints is

$$C(x,t) = C_0 \frac{\cosh x \left(\frac{K}{D}\right)^{1/2}}{\cosh (S_A + b)\left(\frac{K}{D}\right)^{1/2}} + \frac{2}{S_A + b} \cdot \Phi \qquad (7)$$

where

$$\Phi = \sum_{n=1}^{\infty} e^{-(D\beta^2 + K)t} \cos \beta x \left(\frac{(-1)^n D\beta C_0}{D\beta^2 + K} + \int_0^{S_A + b} f(x') \cos \beta x' dx' \right)$$

and

$$\beta = \frac{(2n-1)\pi}{2(S_A + b)}$$

and D and K are the diffusion and reaction rate constants, respectively. Combining equations (3), (4) (5) and (7), and rearranging, the final equation becomes

$$F = \frac{P_m}{4\pi\varepsilon} \int_b^{S_A + b} \left(K_1 C_0 \frac{\cosh x \left(\frac{K}{D}\right)^{1/2}}{\cosh (S_A + b)\left(\frac{K}{D}\right)^{1/2}} + K_2 + \frac{2K_1}{S_A + b} \cdot \Phi \right) x$$
$$x \left(\frac{1}{\sqrt{(x - S_m)^2 + \frac{V}{2\pi(S_A + b)}}} - \frac{1}{\sqrt{(x + S_m)^2 + \frac{V}{2\pi(S_A + b)}}} \right) dx \qquad (8)$$

This equation was programmed on an IBM 7090 digital computer (Stanford University Computation Center) to similate isometric experiments on striated muscle. Since calcium ions are released in pulses from the lateral cisternae in response to muscle stimuli, the solution of equation (8) was carried out in time increments equal to the pulse widths of these stimuli (2 msec). The calcium distribution in the sarcomere at the end of each time increment was used as the initial condition ($f(x)$) for the next solution increment. During these increments, the programme assigned to C_0 one of two values to generate the desired stimulation frequency $\left(\frac{1}{T2}\right)$, an "on" value of $1{\cdot}667 \times 10^{-5}\ (1 - e^{-T2/0.012})M$ or an "off" value of 10^{-8} M. (Because the lateral cisternae are not assumed to be infinite calcium sources, the "on" concentration was reduced as the frequency increased.) Other parameters used in these solutions were $D = 2 \times 10^{-8}$ cm^2/sec, $K = 15$ sec^{-1}, $\varepsilon_\pi = 40$, $S_A = 1\mu$, $S_m = 0{\cdot}825\mu$, $P_m = 4{\cdot}925 \times 10^{-10}$ coulombs/m, P_A(SAT.) $= 2{\cdot}377 \times 10^{-10}$ coulombs/m, $K_1 = 4{\cdot}4 \times 10^{-31}$ m^2 coulomb/ion, $K_2 = -2{\cdot}64 \times 10^{-11}$ coulombs/m, and $V = 3{\cdot}925 \times 10^{-21}$ m^3. The similarities between the actual experimental data and the predictions made by the computer solutions of equation (8) are the subject of the remainder of this article.

Fig. 5 depicts the time course of the active state in the muscle following a single pulse of stimulation[48-53]. The force predicted by the theoretical equation (dashed curve) is compared with the active state as determined by D. E. S. Brown by pressure potentiation studies[54] (solid curve). The active state has a rapid initial onset and a slow decline, which are properties noted in the time history of calcium concentration in the sarcomere volume.

Other features of the active state predicted by the theoretical equation but not shown here are the decline in force and the small increases in peak time and relaxation time as the muscle is stimulated at increasing sarcomere lengths[55-57].

Fig. 6 depicts the length–tension diagram of striated muscle. The muscle, initially stretched to a given length, is rapidly stimulated, and the maximum developed tension is recorded. Curves 1 and 2 are the length–tension diagrams for frog sartorius fibres as experimentally determined by Ramsey and Street[58,59] and Gordon, A. F. Huxley, and Julian[60], respectively. Curves 3 and 4 illustrate two length–tension curves which can be computed on the basis of our electrostatic hypothesis. In curve 3 the actin line density increases linearly from b to $S_A + b$. In curve 4 the line charge increases linearly from b to about $3/4\ S_A$, then remains constant (owing to saturation) over the balance of the filament. By reducing the reaction rate constant (K) in equation (8), other length–tension diagrams having greater developed forces at long sarcomere lengths, similar to those measured by Buchthal[57] and Carlsen, Knappeis, and Buchthal[61], are also predicted by this equation. The maximal isometric force of about 8×10^{-8} g/myosin filament[62,63] is readily developed in our hypothesis with filament line densities less than 5×10^{-10} coulombs/m and interfilament distances of 185–250 Å. The reduction of developed force at long sarcomere lengths arises from the increasing separation of the charge distributions as the muscle lengthens. The fall of tension at short sarcomere lengths occurs as the ends of the myosin filaments enter the regions between the Z-membranes and the charge centres on the actin filaments. Note that the form of the length–tension diagram depends on the ratio K/D in equation (8), while the twitch force depends on a weighted sum of these parameters. Since both K and D would be expected to have a temperature coefficient of the same sign, it would follow that the twitch would be affected more by changes in temperature than would be the tetanus at a given sarcomere length.

In Fig. 7 we have six curves, drawn by a Calcomp plotter in conjunction with a 7090 digital computer, which show the solutions of equation (8) as the frequency of stimulation is increased (sarcomere length, $2{\cdot}2\mu$). It should be noted that although the stimulus duration is only 2 msec, peak force development does not occur for about 7 msec. This lag in peak force development is due to the nature of the diffusion process in the sarcomere and agrees with experimental observations of the active state in striated muscle[48-53]. It should also be noted that as the interval between successive stimuli is reduced, the height of the response to the second stimulus increases; this is the active state counterpart of the force-interval curve measured in living muscle[64,65]. The curves also demonstrate a progressive fusion of the active state force

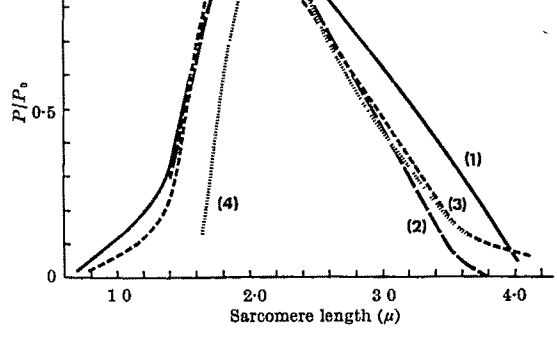

Fig. 6. Length–tension diagrams of striated muscle. Curves (1) and (2), experimental; curves (3) and (4), theoretical prediction by this hypothesis. Curve (1) scaled.

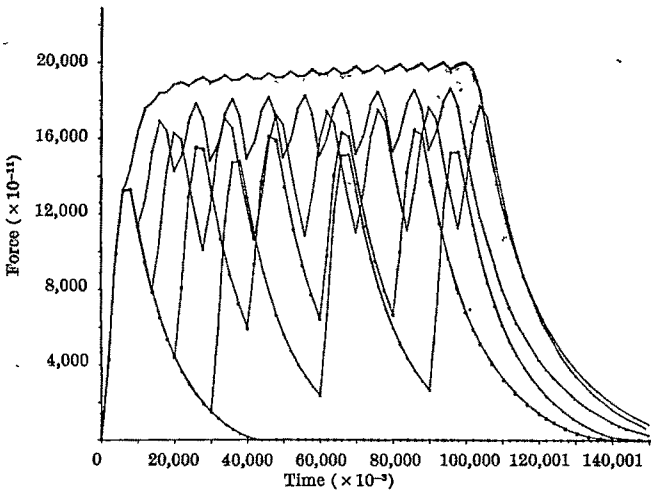

Fig. 7. Theoretical active-state forces predicted by equation (8) at increasing stimulation frequencies.

as the frequency of stimulation is increased, which is again a typical feature of muscle behaviour[57].

Thus the theoretical isometric predictions based on this hypothesis correlate well with the experimentally determined behaviour of striated muscle. These correlations, however, must be interpreted cautiously, because we are predicting the behaviour of a single force-developing element within the sarcomere and the experimental data are taken from single fibres which consist of large aggregations of these force-developing units surrounded by viscous and elastic elements. Nevertheless, for well-ordered muscles such as frog sartorius, at least, the extrapolations seem reasonable in many cases.

In summary, we have proposed a mechanism by which the force of muscular contraction could be developed in striated muscle. The mechanism does not depend on a mechanochemical interaction of the actin and myosin filaments, but rather assumes that the *F*-actin filaments, neutrally charged at rest, assume a positive line charge during stimulation, and thus attract the negatively charged *L*-myosin filaments in the manner of an electrostatic solenoid. Calcium ions, released and later accumulated again by the elements of the sarcoplasmic reticulum in response to muscle stimuli, are assumed to be responsible for these alterations in charge density on the actin filaments and thus regulate the magnitude and form of the forces developed in the sarcomere.

We thank A. Burzio for assistance in the digital computer programming.

ELECTROSTATIC POTENTIAL MODEL FOR THE SOLUBILITY OF THE ALKALI HALIDES IN WATER

By MICHAEL HACSKAYLO
Physical Electronics Laboratory, Melpar, Inc., Falls Church, Virginia

THE purpose of this article is to present a new relationship between the solubility of the alkali halides and the ionic radii. It was observed that a linear relationship exists between the solubility of the alkali halides and the difference of the ionic radii for any given cation family. It will be shown that this relationship is compatible with the electrostatic potential model of charged spheres.

The mechanisms involved in the solubility of the alkali halides in water has been a subject of discussion for nearly five decades. The Born equation[1] for the crystal lattice

energy is fundamental to the solubility problem and thus has provided the stimulus for numerous investigations in this field. Grimm[2] studied the dependency of the solubility both on the structure of the external electron shells and on the charges and the radii of the ions. Fajans[3] showed that the deformation of the ions of the alkali halides explained some of the variations of the physical and chemical properties of the salts, while the deformation of the ionic sheaths was found to correspond to some of the variations of the solubility of the alkali halides[4]. Balce[5] obtained a solubility law based on the electrolytic decomposition potential. In an investigation of the solubility processes of the alkali halides, Campbell[6] noted that the minima of solubilities of the salts in water corresponded to the values of nearly equal anion and cation radii. These investigations have indicated some general, but not, however, always consistent, rules.

The Born–Haber cycle describes a nearly complete analytical model for evaluating the energy changes of the solubility process of a solid in a liquid. A comprehensive thermodynamic treatment, based on the Born–Haber cycle, was described by Ladd and Lee[7]. In the Born model, the heats of solution (hydration) are considered to be exothermic if the lattice energy is greater than the energy required for solution, and endothermic if the reverse energy balance occurs[8]. The relationship between the physical properties of ionic crystals and the dimensions of ions comprising the crystals was emphasized by Pauling[9]; he did not, however, discuss the solubility of the salts.

In this article, the values of the saturated solubilities and ionic radii have been taken from previous reports. The radii of the anions and cations are denoted by R_a and R_c respectively, and are shown in Table 1. These values, taken from Goldschmidt, are discussed by Seitz[10], and he ascribes the values as being self-consistent to within about 5 per cent. The solubility values for each of the alkali halide salts were taken from Sidgwick[11]. These were recalculated in moles/100 g water and are shown in Table 2.

Table 1. IONIC RADII ACCORDING TO GOLDSCHMIDT*

	Å		Å
Fluorine	1·33	Lithium	0 78
Chlorine	1 81	Sodium	0 98
Bromine	1·96	Potassium	1 33
Iodine	2 20	Rubidium	1·49
		Caesium	1 65

* See ref. 10.

Table 2. SOLUBILITY OF THE ALKALI HALIDES IN MOLES/100 G WATER AT 25° C*

	Fluoride	Chloride	Bromide	Iodide
Lithium	0 005	1·02	1·88	1 23
Sodium	0 098	0 61	0·91	1·22
Potassium	1 65	0 46	0 55	0 87
Rubidium	1·26	0·75	0 65	0 74
Caesium	2 40	1·09	0 58	0 27

* See ref. 11.

Although not shown here, a plot of the solubilities as a function of $(R_a - R_c)$ exhibits a linear function for the cation families. However, Fig. 1, a plot of the solubility as a function of $\frac{1}{R_aR_c}(R_a - R_c)$, shows a similar relationship but a better fit. The $\frac{1}{R_aR_c}(R_a - R_c)$ values are listed in Table 3. A similar plot (not shown here) of the solubility as a function of $\frac{1}{R_cR_a}(R_c - R_a)$ did not have a linear relationship for the halogen families. Thus the linear relationship is apparently restricted to the cation families.

The four caesium salts fall on a straight line; rubidium fluoride, rubidium chloride and rubidium bromide lie in a straight line, rubidium iodide does not; potassium iodide and potassium chloride is a straight line with a given slope, while potassium bromide and potassium iodide lie on another straight line of equal but opposite slope; sodium fluoride does not lie on the straight line of sodium chloride, sodium bromide and sodium iodide; lithium fluoride, lithium chloride and lithium bromide lie on a straight line, but lithium iodide does not. For the rubidium and sodium families, a straight line was drawn through three points with a slope of $\mp\alpha$ and another straight line drawn through the fourth point with a slope of $\pm\alpha$.

The empirical solubility equation can be expressed as

$$S = \alpha\left[\frac{1}{R_aR_c}(R_a - R_c) + L_s\right] + S_0 \qquad (1)$$

where S is the saturated solubility in moles/100 g water, α the slope in moles-Å/100 g water, and S_0 a constant in moles/100 g water. The values of the constants for a good fit of equation (1) are listed in Table 4. The full significance of the constants cannot be evaluated at this time.

Table 3. $\frac{1}{R_aR_c}(R_a - R_c)$ VALUES OF THE ALKALI HALIDES (Å^{-1})

	Fluoride	Chloride	Bromide	Iodide
Lithium	0 52	0 56	0 60	0 64
Sodium	0 27	0 46	0 51	0 56
Potassium	0 00	0 26	0 32	0·39
Rubidium	−0 08	0·12	0·16	0 21
Caesium	−0 14	0 05	0 10	0 16

Table 4. EMPIRICAL CONSTANTS DETERMINED FROM THE EXPERIMENTAL DATA TO FIT EQUATIONS (1) FOR EACH CATION FAMILY

	$\left(\frac{\alpha}{\text{Moles-Å}/100\text{ g water}}\right)$	L_s (Å^{-1})	S_0 (Moles/100 g water)
Lithium	22 3	−0 517	0
Sodium	∓5 82	−0 312	−0·22
Potassium	∓4·55	−0 278	0 38
Rubidium	∓2 58	−0·165	0 61
Caesium	−7·88	−0·175	0

The two branches shown in Fig. 1 and the positive and negative slopes for the sodium, potassium, and rubidium families indicate a second-order function for equation (1). However, owing to the linearity exhibited by the branches, the positive values of $\alpha[(R_a - R_c) + L_s]$ will be con-

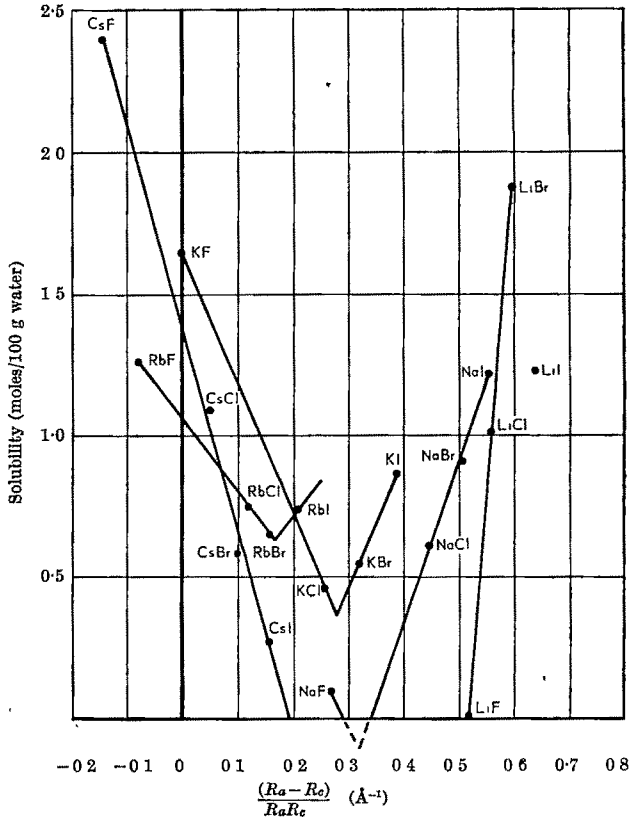

Fig. 1. A plot of the experimental solubility of the alkali halides in moles/100 g water as a function of the difference of the reciprocal of the ionic radii in Å^{-1}.

sidered only when the appropriate signs for α are taken in this discussion.

A form of equation (1) can be obtained from an approximation based on the electrostatic potential between two charged spheres. Although the water molecule has a dipole moment, it will be assumed here that during the solvation process, the water molecule behaves as either a positive or negative ion (that is, positive if a negative ion is hydrated, and negative if a positive ion is hydrated). The electrostatic potential at the shell of the cation during solvation by the water molecule is

$$V_1 = K_1 \left(-\frac{1}{R_{w-}} + \frac{1}{R_c} \right) \quad (2)$$

and for the anion solvation, the potential is

$$V_2 = K_2 \left(\frac{1}{R_{w+}} - \frac{1}{R_a} \right) \quad (3)$$

where K_1 and K_2 are constants of the medium, and R_{w+} and R_{w-} are the water molecular radii when behaving as a positive or negative "ion" respectively. Assuming $K_1 = K_2$, the energy available per molecule for solvation in water is:

$$E = V_1 + V_2 = K \left[\frac{(R_a - R_c)}{R_a R_c} + \left(\frac{1}{R_{w+}} - \frac{1}{R_{w-}} \right) \right] \quad (4)$$

The number of molecules of solute, measured in moles per given volume of water, would be proportional to E. Thus equation (1) can be implied by letting $L_s = \left(\frac{1}{R_{w+}} - \frac{1}{R_{w-}} \right)$.

The form of equation (1) is in contrast to the Born treatment, which is a function of the sum of the reciprocal of the ionic radii[8] for the solubility of the alkali halides in water.

It is noted that heat of solution does not implicitly enter equation (1). The heats of solution of the alkali halides, endothermic or exothermic, do not exhibit any consistent pattern in the $(R_a - R_c)$ relationship. The salts on the heavier halogen side, lithium chloride, lithium bromide, lithium iodide, sodium iodide and potassium iodide are exothermic, whereas the fluorine salts, potassium fluoride, rubidium fluoride and caesium fluoride, are also exothermic. For the heavier halogen salts, it is noted that the face centred crystalline structures exhibit anion–anion contact as determined by the ionic ratios $\frac{R_c}{R_a} \leqslant 0{\cdot}414$ (ref. 12). The ionic ratios of the alkali halides are listed in Table 5.

The R_c/R_a values of lithium chloride, lithium bromide, lithium iodide and sodium iodide agree with the anion–anion contact model within the error expected of the radii values[10]. It is therefore postulated that for the heavier halogen salts, the exothermic heat of solution results from the anion–anion repulsion force during the solvation process. The R_c/R_a value of potassium iodide at 0·61 does not fit the anion–anion contact model and cannot at this time be explained.

Table 5. R_c/R_a VALUES OF THE ALKALI HALIDES

	Fluoride	Chloride	Bromide	Iodide
Lithium	0 59	0·43	0 40	0 35
Sodium	0 74	0 54	0·50	0 44
Potassium	1·0	0 74	0 68	0·61
Rubidium	1·12	0 84	0 76	0 68
Caesium	1·24	0·91	0 84	0·75

The exothermic heats of solution accompanying potassium fluoride, rubidium fluoride and caesium fluoride, can be explained as follows. During the solvation process, the attraction of the water molecules to the cations is greater than that to the anions[13,14]. Thus it is assumed that for cations the radii of which are equal to or larger than the anion radii, the cation would hydrate (dislodge from the crystal lattice) before the anion. The anion–anion repulsion force would then predominate during the solvation of the cation and thus the solvation would exhibit an exothermic heat of solution. Potassium fluoride, rubidium fluoride and caesium fluoride are exothermic; $\frac{R_c}{R_a} \geqslant 1{\cdot}00$ for each and thus satisfies the conditions of the above postulate.

The endothermic heats of solution would then be explained from the converse of the anion–anion repulsion force model. The salts of which the molecules exhibit attractive forces during solvation would require energy for hydration, and thus the process would lose heat.

Two conclusions can be drawn from these observations: first, the solubility of the alkali halides in water can be expressed as a function of the differences in ionic radii based on the hard shell electrostatic potential model; second, the exothermic heats of solution result from anion–anion repulsion forces present in the crystal lattice during the solvation process and are apparently indirectly dependent on the solvation process itself. The endothermic heats of solution are explained, conversely, as arising from the attractive force present in the crystal lattice during the solvation process.

PRESENCE OF A SERIES OF PLASTOQUINONES IN PLANTS

By DR. W. T. GRIFFITHS, J. C. WALLWORK and DR. J. F. PENNOCK

Department of Biochemistry, Johnston Laboratories, University of Liverpool, Liverpool 3

CHROMATOGRAPHIC fractionation of plant lipids has revealed the presence of a family of compounds, the plastoquinones (PQ), members of which exhibit the same ultra-violet absorption characteristics, maxima at 255 and 263 mμ, although they are chromatographically distinct. Crane[1] originally described plastoquinone-9 (PQ-9 or PQ *A*) as 2,3-dimethyl-5-solanesylbenzoquinone from spinach chloroplasts and since then this source has also yielded PQ-3 (ref. 2) (with a farnesyl side chain) while PQ-4 (geranylgeranyl side chain) has been found in horse-chestnut leaves[3]. Three more plastoquinones, designated PQ *B*, PQ *C* and PQ *D* to distinguish them from PQ *A*, have been found in spinach chloroplasts[4–6]. PQ *B* was similar in chromatographic polarity to PQ *A*, whereas PQ *C* and PQ *D* were much more polar in nature and were shown to have a hydroxyl group by infra-red

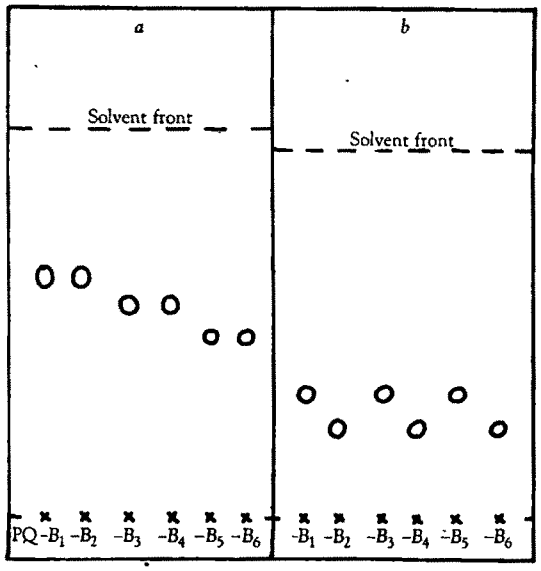

Fig. 1. Adsorption (*a*) and partition (*b*) thin layer chromatograms of purified "PQ *B*" type quinones from *Ficus*. About 10 μg of each sample was applied. Solvent: adsorption, 12 per cent di-iso-propyl ether in light petroleum. Partition, 2·5 per cent water in acetone. Stained with Emmerie-Engel reagent after reduction with sodium borohydride.

spectroscopy[7]. Samples of PQ *B*, PQ *C* and PQ *D* have been examined by mass spectrometry[8] and PQ *B* was reported to have two hydrogens less than PQ *A*, while PQ *C* and PQ *D* had an oxygen atom more than PQ *A*. Thus it was suggested[8] that PQ *C* (or PQ *D*) could be a hydroxy PQ *A* or a hydrated PQ *B*.

In the present examination of plant lipids a column fraction of similar polarity to PQ *B* has been obtained which on adsorption and partition thin layer chromatography could be resolved into six distinct components each with the 255, 263 mμ spectrum. It is proposed to call these compounds PQ B_1, PQ B_2, PQ B_3, PQ B_4, PQ B_5 and PQ B_6; identification of one or all of these compounds with PQ *B* as previously described awaits further study. It has also been shown by thin layer chromatography that there are at least six distinct compounds (each with the 255, 263 mμ chromophore) eluted from a column in the PQ *C*–PQ *D* region. The assignment of trivial names for these quinones is difficult because we cannot identify them with Crane's PQ *C* or PQ *D* specifically. On thin layer chromatography the six quinones are split roughly into two groups of three which may correspond broadly with PQ *C* and PQ *D*. As PQ *C* was the first "polar" plastoquinone to be described[4] we will call the six "polar" plastoquinones described here PQ C_1, PQ C_2, PQ C_3, PQ C_4, PQ C_5 and PQ C_6 for relative simplicity. While it is possible that there is some relationship between the two groups "PQ *B*" and "PQ *C*" we do not wish to imply any connexion between PQ B_1 and PQ C_1, etc.

Leaf tissues were obtained from the University Botanical Gardens, Ness, a few hours before use. Elder (*Sambucus nigra*) was examined by one of us (W. T. G.) in some earlier work on "PQ *B*" and so values for "PQ *C*" were not obtained for this tissue. Again the "PQ *B*" fraction from *Gossypium* contained a congener which intensively absorbed ultra-violet light and which was difficult to remove; this tissue was eliminated from the "PQ *B*" survey. The leaves were extracted by homogenizing in acetone and diethyl ether/light petroleum (40°–60° C) was added to the filtered extract and the acetone was washed out with water. The extracts were chromatographed on acid-washed alumina (Woelm) deactivated to Brockmann Grade 3 and six fractions were collected, 0·25 per cent diethyl ether/light petroleum (E/P), 1 per cent E/P, 3 per cent E/P, 8 per cent E/P, 20 per cent E/P and ether. PQ *A* was present in the 1 per cent E/P fraction, "PQ *B*" was in the 3 per cent E/P fraction while 20 per cent E/P eluted the "PQ *C*–PQ *D*" material. All three of these fractions exhibited ultra-violet absorption at 255, 263 mμ. Plastoquinone *A* was estimated by reduction with sodium borohydride using a $\Delta\varepsilon$ mol. of 18,700. Chlorophyll was determined by the method of Arnon[9].

The 3 per cent E/P fractions, which contained "PQ *B*" and α-tocopherol as the major ultra-violet-absorbing components, were chromatographed quantitatively on preparative thin layers (500μ) of silica-gel *G* impregnated with "Rhodamine 6 *G*" and developed in chromatotanks with 12 per cent di-iso-propyl ether/light petroleum. Under ultra-violet light[10] three distinct bands were seen migrating in front of α-tocopherol on the developed chromatograms and these were eluted separately and rechromatographed on paraffin-impregnated silica-gel *G* layers (250μ) developing with 97·5 per cent aqueous acetone in the saturation chamber of Davies[11]. The developed plates were sprayed with 0·001 per cent fluorescein in ethanol and examined under ultra-violet light. In this system each of the three bands from the adsorption plates separated into two fractions (see Fig. 1) and these were eluted.

The samples were chromatographed on columns of alumina (3 g), light petroleum eluting the paraffin and 6 per cent E/P bringing off the quinones. The quinone content of each fraction so obtained was estimated by reduction with sodium borohydride in ethanol (assuming $\Delta\varepsilon$ mol. at 255 mμ of 18,700 for all PQs). All six quinones possessed the typical PQ spectrum, $\lambda_{max.}$ 255 mμ, inflexion 263 mμ and gave the same isosbestic points at 232 and 276 mμ on reduction.

A small sample of the 20 per cent E/P fraction (0·3–0·5 mg) was subjected to two-dimensional thin layer chromatography with 15 per cent ether/benzene as solvent in both dimensions. The developed chromatogram was sprayed with borohydride solution, acid and then Emmerie–Engel reagent[12] and the quinones were thus detected as pink spots. Seven quinones were detected in a diagonal line across the plate (see Fig. 2). There was one relatively polar spot and two groups of three. Two portions of each sample were chromatographed and the developed chromatograms were sprayed with 0·001 per cent fluorescein and the quinones seen in ultra-violet light as dark areas on a fluorescent background. The silica-gel corresponding to each spot was scraped off

* Quinone values expressed as μmoles × 10^3/g fresh weight.
† Chlorophyll values expressed as mg/g fresh weight.
‡ Unidentified lipid interfered with borohydride reduction.

(material from the two plates was bulked) and extracted twice with ether. The absorption spectrum of each fraction in ethanol was examined and the most polar spot showed maxima at 262 and 269 mμ which is indicative of α-tocopherol quinone. All the other six spots gave spectra with maxima at 255 mμ and inflexions at 263 mμ. The plastoquinones and α-tocopherol quinone were determined by borohydride reduction using the Δεmol. figures of 18,700 at 255 mμ for PQs and 17,840 at 262 mμ for α-tocopherol quinone.

Table 1 shows the content of "plastoquinones *B*" in the various leaf samples. The total "PQ *B*" level was in general much lower than that of PQ *A* and varied from 0·0036 μmole/mg chlorophyll in *Stephania* to 0·102 μmole/mg in *Ficus*. *Pinus* was exceptional in that the total "PQ *B*" (28·0 μmole/g fresh weight) was of the same order as PQ *A* concentration (29·4 μmole/g fresh weight). The relative amounts of each "PQ *B*" type quinone varied between tissues; however, the PQ B_1 plus PQ B_2 fraction (eluted together from adsorption thin layer chromatogram) accounted for the highest proportion while the PQ B_5 fraction always occurred at the lowest level.

All the 20 per cent fractions gave similar two-dimensional thin layer chromatograms showing the same seven spots. The quinones were (in order of increasing polarity) PQ C_1, PQ C_2, PQ C_3, PQ C_4, PQ C_5, PQ C_6 and α-tocopherol quinone. Table 2 shows the content of the quinones in the leaf samples. The ratio of PQ *A* to "PQ *C*" varied; for example, in *Passiflora* and *Ixora* there was more "PQ *C*" than PQ *A* and in *Gossypium* the levels were about the same. In *Urtica* and *Fuchsia*, however, there was very much more PQ *A* than "PQ *C*". α-Tocopherol quinone was found to be present at levels generally much lower than those of PQ *A* and lower than the total "PQ *C*". In general PQ C_2 was in the highest amount in the "PQ *C*" group and there were relatively large amounts of PQ C_5 in some cases. There was usually much more "PQ *C*" in a plant than "PQ *B*". All the plastoquinones in the "*C* group" gave isosbestic points at 231 and 307 mμ on reduction of the quinone to quinol with borohydride and these positions are similar to those recorded for PQ *C* and PQ *D* by Threlfall, Griffiths and Goodwin[7]. These isosbestic points are slightly different from those given by the "PQ *B*" components, and the reason may be that, because of the methods used, the "PQ *B*" materials were purified to a greater extent.

It might be argued that this multiplicity of "PQ *B*" and "PQ *C*" fractions is merely a reflexion of the instability of the materials and that many of the PQs reported here are artefacts. However, the various chromatograms obtained could always be reproduced and there was no indication of changes in pattern; furthermore, the presence of six quinones in each group cannot be without some significance of familiarity.

One of us (J. C. W.) is the recipient of a Science Research Council research studentship. Part of the equipment used in this work was provided by a grant from the Science Research Council. We thank Prof. R. A. Morton for his help and interest in this work.

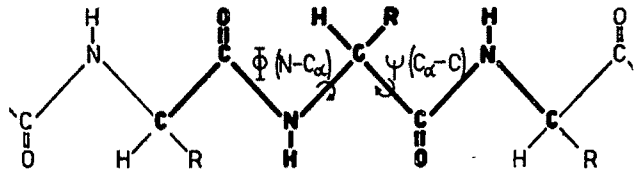
STEREOCHEMICAL CODE OF AMINO-ACID RESIDUES: THE MOLECULAR CONFORMATION OF GRAMICIDINE *S*



By PROF. A. M. LIQUORI, P. DE SANTIS, A. L. KOVACS and L. MAZZARELLA

Centro Nazionale di Chimica delle Macromolecole (CNR) Sez. III, Institute of Chemistry, University of Naples

THE possible conformations of helical polypeptide chain with amino-acid residues in equivalent positions are restricted by their van der Waals interactions[1–3]. The limited number of permissible conformations includes those established experimentally by X-ray analysis.

We have published contour maps showing the conformational free energy of helical poly-L-alanine and poly-L-proline as a function of the angles of rotation about the bonds adjacent to the α-carbon atoms. Figs. 1 and 2 are the same maps redrawn according to the new con-

vention[4]. The maps show that only five helical configurations are sterically permissible ($R\alpha,\beta,\gamma,\delta$, $L\alpha$). Amino-acids with bulky side-chains, such as valine, threonine or isoleucine, which are repeated indefinitely, can distort any of these helices, but especially the α-helix[2,3]. Accordingly, only a restricted number of conformations are permissible for a polypeptide chain made up of non-identical residues. The chain, which would not necessarily consist of conformationally equivalent residues, would have a tertiary structure defined by the sequence of conformational states of its component residues. We have calculated the potential energy of the following unit:

This does not correspond to an amino-acid residue but to that part of the chain the conformation of which is determined by two angles of rotation $\psi_{C_\alpha-C}$ and Φ_{N-C_α} adjacent to the α-carbon atom. The energy map obtained in this way makes it possible to select the most stable conformation of an L-amino-acid residue in a polypeptide chain independent of its nearest neighbours in the sequence. Such a calculation shows that the only conformational states permissible for any one "unit" are those which we shall call $R_{a,b,c,d}$, La, shown in Fig. 3, which generate by repetition the helical conformations $R\alpha,\beta,\gamma,\delta$, $L\alpha$ permissible for homopolymers of L-amino-acids. However, the minima of the energy map calculated without the condition of conformational equivalence are broader because the co-operative interactions which stabilize a helix are absent. Nevertheless, this procedure

Proline	O	1·7	−0·2	−0·2
	Cβ	1·6	−2·3	1·4
	Cγ	0·6	−3·1	1·5
	Cδ	−0·5	−2·2	2·4

may enable the most stable conformations to be identified and a tertiary structure to be predicted on a rational basis from the primary sequence. Such a method was tested for the cylic decapeptide gramicidine *S*.

The ten residues are identical in pairs (Fig. 4*a*). We determined the sequence of permissible conformational states that can be assigned to the amino-acid residues in order to satisfy as closely as possible the condition of ring closure. Such states are indicated in Fig. 4*a*. It should be noted that for D-Phe we have chosen a state *c** which is enantiomorphous of state *c* permissible for L-amino-acid residues. Starting with this model and adjusting it so as to close the ring, the structure shown in Fig. 4*b* was obtained. This consists of two antiparallel single turns of right-handed α-helix bridged by proline and phenylalanine. Each helical section contains one hydrogen bond between the first and fourth amino-acid residues. A dyad axis perpendicular to the direction of the helix relates one half of the molecule with the other. The atomic co-ordinates with respect to the axial system of Fig. 4*b* are given in Table 1. The dimensions of the molecule agree with those given by Schmidt *et al.*[5] on the basis of a preliminary X-ray analysis.

MICROPULSATION MEASUREMENTS DURING THE PUGET SOUND EARTHQUAKE OF APRIL 29, 1965

By JAMES F. KENNEY and LEONARD E. JOHNSON*

Boeing Scientific Research Laboratories, Seattle, Washington

On April 29, 1965, a severe earthquake occurred in the Puget Sound area which was later reported to be about magnitude seven on the Richter scale. Algermissen and Harding[1] have recently published the location and magnitude of the earthquake as determined by an analysis of seismic records from an extensive array of seismometers and from damage surveys in the area. These authors have also given a description of the geological setting and history of seismicity in this area.

The purpose of this article is to report an interesting observation made by a pair of three-component micropulsation detectors located near the epicentre. Normally this equipment is used to measure rapid changes in the Earth's magnetic field induced in a stationary induction loop. If the magnetic field is uniform and unchanging, an electromotive force (E.M.F.) can also be induced in the coils if they undergo a rotation, but not if they undergo a simple translation. The three loops are shown schematically in Fig. 1, and their expected response to the compressional or *P* wave and the distortional or *S* wave is indicated. The *P* wave arrives first and induces a rocking motion in the vertically mounted coil ($\dot{H}_z$), but not in the two coils ($\dot{H}_x$ and $\dot{H}_y$) lying flat on the Earth's surface. As the slower *S* wave passes, the Earth's surface tilts and induces rotation in all three coils.

The two stations are located near Tulalip, Washington (48·077° N., 122·192° W.), and Cougar Mountain, Washington (47·531° N., 122·125° W.). At Cougar Mountain, two telluric current probes (E_x and E_y) were also functioning, and their response was similar to that of $\dot{H}_x$ and $\dot{H}_y$ at the same station. The signals from the three magnetic coils at each station and from the two telluric current probes at Cougar Mountain were amplified, telemetered to Seattle, and recorded on a pair of slow-speed (15 cm/h) magnetic tape recorders. Timing marks derived from the local power lines were also recorded hourly. The data were later recovered and analysed by playing the tapes back at high speed on a recording oscillograph. A reproduction of these data is given in Fig. 2.

The E.M.F.s induced in the moving coils were sufficiently large to cause saturation in the amplifier chain, so that details of the Earth movement cannot be derived from these data. However, it can be seen that the $\dot{H}_z$ coils responded to both the *P* and *S* waves, whereas the $\dot{H}_x$

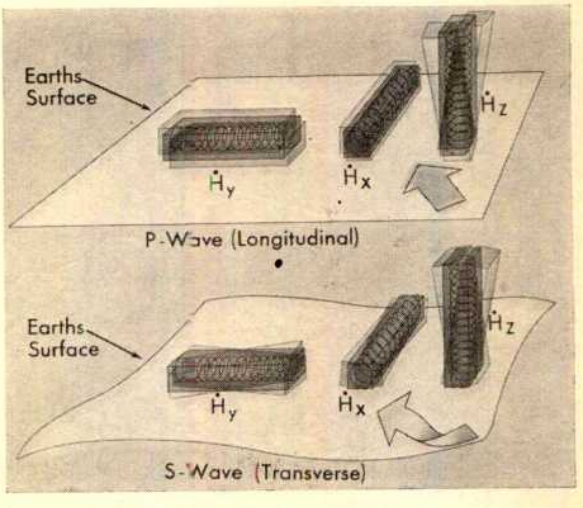

Fig. 1. Schematic representation of the three induction loops and their response to *P* and *S* waves.

* Permanent address: University of California, San Diego, La Jolla, California.

and $\dot{H}_y$ coils responded only to the S waves. It is also apparent that the signals arrived first at Cougar Mountain. The separation of the P and S waves is particularly clear in the Tulalip records, and the delay time for the arrival of the S wave after the P wave is about 11·25 sec. Because the three magnetic components at Tulalip were recorded on the same magnetic tape as one telluric current component (E_x) at Cougar Mountain, a reasonably accurate measurement of the relative arrival times of the wave at the two stations was also possible. As can be seen in Fig. 2, the S wave arrived at Cougar Mountain just as the P wave arrived at Tulalip.

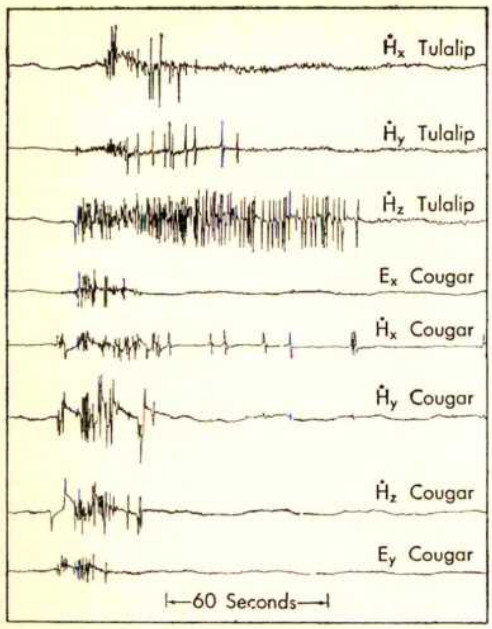

Fig. 2. Recordings of the magnetic field and earth-current detectors at Tulalip and Cougar Mountain at the time of the Puget Sound earthquake, April 29, 1965.

For the purposes of this article, it will be assumed that the velocity of the P wave, v_p, is 6 km/sec, and that the velocity of the S wave, v_s, may be represented[2] by

$$v_s = \frac{v_p}{\sqrt{3}} \qquad (1)$$

Using these velocities and the times already mentioned, it is possible to deduce from equation (2)

$$D_T = 6T = (6/\sqrt{3})(T + 11{\cdot}25) \qquad (2)$$

that the distance of Tulalip from the epicentre, D_T, was about 92 km, and the P wave arrived there at $T = 15{\cdot}4$ sec after the earthquake. Because this is the time for arrival of the S wave at Cougar Mountain, it is possible to determine the separation distance, D_C, of that station from the epicentre. Hence

$$D_C = (6/\sqrt{3})(15{\cdot}4) \simeq 53 \text{ km} \qquad (3)$$

The separation distances of the two stations from the epicentre (122·3° W., 47·4° N., 59 km depth) published by Algermissen and Harding[1] can also be computed. These distances are 96 km and 62 km for Tulalip and Cougar Mountain, respectively, and are shown in Table 1.

Considering how difficult it is to determine the exact time of onset of a P or S wave, and the assumptions that

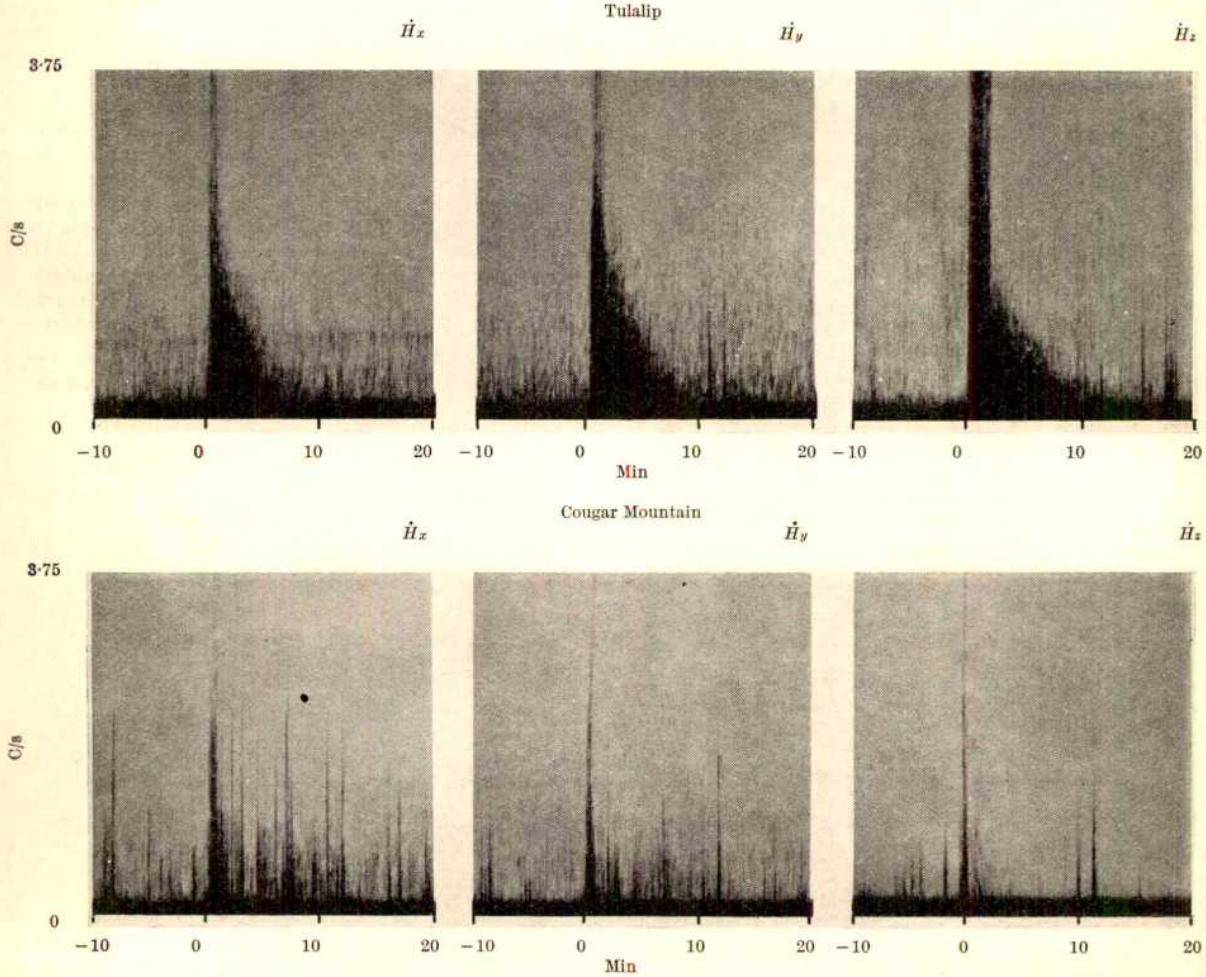

Fig. 3. Spectral analysis of the earth motion at the two stations during the Puget Sound earthquake, April 29, 1965.

Table 1. SEPARATION OF THE STATION FROM THE EPICENTRE

Station	Location	Epicentral separation according to magnetic records	Epicentral separation (Algermissen and Harding (ref. 1))	Residual distance
Cougar Mountain	47·531° N 122·125° W	53 km	62 km	9 km
Tulalip	48·077° N 122·192° W	92 km	96 km	4 km

were made concerning the velocities of the P and S waves, the residuals are certainly within the limits of error of this experiment.

Spectral analysis of Earth movement. The magnetic tapes were also played back on a 'Sonagran' spectrum analyser to determine the frequency content of the Earth movement as a function of time after the earthquake. These data are presented in Fig. 3. It can be seen that the motion was considerably smaller and terminated much more rapidly at Cougar Mountain than at Tulalip. Tulalip is located on a sedimentary area, whereas the Cougar Mountain station is situated on top of an extensive coal deposit with considerable surface outcroppings.

Magnetic precursors. In recent years several observations have been reported of magnetic changes before earthquakes. These seem to fall into two main classes: first, very slow changes which are detected as an increase in the total magnetic flux density at the surface of the Earth over a period of several years before the earthquake[3]; and second, very rapid disturbances of large magnitude in the hours just preceding the seismic disturbance[4]. Breiner[5] has reported actual measurements of this type for very small earthquakes in Nevada in 1962.

The general explanation for these phenomena is usually given as a change in magnetic permeability of the piezomagnetic rock resulting from changes in stress before the earthquake. It is clear that the pattern of magnetic disturbance before an earthquake will be difficult to predict because of the lack of knowledge of the magnetostrictive properties of the underlying rock, and because of the complicated behaviour of the stress distribution before and after faulting.

Because the micropulsation equipment described in this article responds to a time rate of change of the magnetic flux density, it is incapable of measuring any long-term variation. Stacey and Westcott[6] have recently discussed the limit of observability of the seismomagnetic effect due to local variations in geomagnetic disturbances. Our two stations are unevenly spaced near the epicentre, and for this reason we are in a very favourable position to detect any rapid variation that may have taken place and discriminate effectively against natural micropulsation activity.

Rather large natural micropulsation activity was evident at both stations after the magnetic storm of April 17, 1965, but the period just preceding the earthquake was exceptionally quiet. It was not possible to detect any magnetic perturbation which could be considered to have arisen from a seismomagnetic effect before the earthquake. Of particular interest is the fact that no magnetic disturbance was detected at the instant of the earthquake. If any magnetic disturbance was present, it was buried in the system noise. In all models based on the response of magnetostrictive rock to changing stress, and in the measurements of Breiner[5], a large magnetic signal would be generated at the instant the stress was relieved by the Earth movement. The fact that no effect was noted at the exact time of the earthquake makes it very unlikely that any appreciable change in the local magnetism had occurred before the earthquake either in a very slow build-up or in an abrupt fashion.

Because the noise level of the amplifier chain corresponds approximately to 2 milligammas/sec, we may set this as an upper limit to the time rate of change of magnetic flux density at the detectors at the instant of the earthquake. Assuming also that the magnetic impulse caused by the relaxation of piezomagnetic rock would be generated in a period less than a couple of seconds, it can be inferred that the upper limit on the maximum change of the Earth's magnetic field at the time of the earthquake was 10^{-2} gamma, and that the upper limit on the dipole moment of the stressed region was $2{\cdot}5 \times 10^{13}$ C.G.S. E.M.U. This is smaller than the value derived by Breiner[5] for a microseism in Nevada.

Thus in summary, the E.M.F.s induced in micropulsation coils have been analysed to compute an epicentre and to look for possible magnetic signals generated by the Puget Sound earthquake of April 29, 1965. The epicentre calculated by this method agrees with that published by Algermissen and Harding[1] within the limits of experimental error. The search for magnetic precursors yielded negative results. The upper limit to the change of dipole moment of the stressed region has been determined to be $2{\cdot}5 \times 10^{13}$ C.G.S. E.M.U. The fact that the focus was so deep may explain the lack of any appreciable effect. The results of this experiment indicate that, at least in this area, the possibility of using the piezomagnetic effect as a useful pre-indication of earthquake activity is rather remote.

We thank F. G. Marshall of the Boeing Company for many useful discussions and comments.

TIME OF CHIASMA FORMATION IN RELATION TO THE TIME OF DEOXYRIBONUCLEIC ACID SYNTHESIS

By DR. S. A. HENDERSON
Department of Genetics, University of Cambridge

IN recent years interest in hypotheses to explain genetic recombination, or chiasma formation, has increased. This is in part due to the increasing volume of abnormal crossing-over data which high resolution microbial genetic systems have been providing and in part due to the fact that studies on chromosome chemistry and ultrastructure are beginning to converge and provide hope that an understanding of recombination phenomena in molecular terms may not be too distant. The purely mechanical torsion hypothesis[1] is no longer satisfactory, for it is unable to account for the molecular precision with which crossing-over occurs, and until recently the most widely accepted hypothesis, particularly to explain microbial recombination results, was the copy-choice hypothesis[2,3]. Greatly modified from the form in which it was originally suggested by Belling[4], this entails a synthetic error at the time that new chromatids are being synthesized. The theoretical and practical limitations

of this hypothesis are considerable when applied to semi-conservative DNA replication and to chromosome behaviour in "higher" organisms, however[5], and many modifications have been suggested to circumvent some of these difficulties. Doubt was first thrown on the tenability of the copy-choice hypothesis when it was discovered that recombination in virus *lambda* of *Escherichia coli* involved "chromosome" breakage and could apparently take place in the absence of DNA replication[6,7]. Though proof was not presented that recombination could not also accompany replication, particularly in other systems, faith in copy-choice was certainly shaken. More recent work, including the observations reported below, collectively show that the copy-choice hypothesis must now be discarded.

In the present experiments, which were designed to test the relation between the time of chiasma formation and the time of DNA synthesis, use was made of the fact that an environmental change, in the form of high-temperature treatment, will modify chiasma formation in locusts in a predictable fashion. Minutes before beginning such a treatment, cells undergoing DNA synthesis were labelled with radioactive thymidine. Labelled stages were identified autoradiographically and the time taken for labelled cells to reach diplotene and metaphase I compared with the time taken for chiasma frequency to be modified at these stages of meiosis.

The experimental material used was the desert locust, *Schistocerca gregaria*, for my earlier studies have established both the normal chiasma properties of this species at male meiosis[8] and the manner in which these are modified when the chiasma frequency is greatly reduced by high temperature treatment at a constant 40° C[9,10]. Three different labelling experiments were carried out, two involving heat treatments and one involving control temperature (30° C) alone. These may best be described separately.

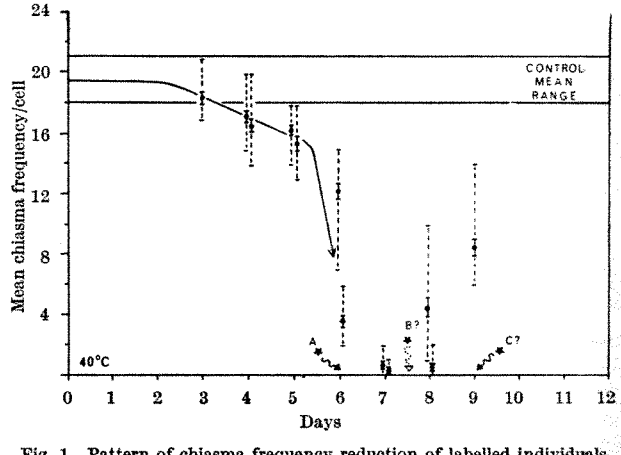
In the first experiment twelve young adult male locusts were injected with tritiated thymidine (6-$T(n)$ specific activity 24·8 c./mmole). This was provided in an isotonic saline to reduce any effects of osmotic shock. Each locust received 0·02–0·025 ml. (about 10 μc.) abdominally, without anaesthesia. The locusts were then placed in an incubator maintained at 40° C and fed twice daily on fresh rye seedlings and bran. They received no light except during feeding times. One individual was taken on the third and ninth days of heat treatment, two on the fourth, fifth, sixth, seventh and eighth days. The testes were removed by vivisection, cleaned of fat body and fixed in acetic-alcohol (1 : 3). Autoradiographs were made from Feulgen-stained squash preparations of part of the testes using 'Kodax *AR*10' stripping film. The exposure time was 50 days. The remainder of the testis material was refrigerated and, once satisfactory autoradiographs had been obtained, chiasma frequencies were scored in propionic-orcein squash preparations made from this material. Chiasma frequencies were scored at diplotene when high and at metaphase I when very low (see refs. 9 and 10 for reasons). Twenty cells from each individual were scored and standard deviations and means calculated.

A constant temperature of 40° C greatly reduces chiasma frequency in this species and can lead to complete failure of bivalent formation. There is an initial time lag of several days before the expression of this effect, however, the most drastic reduction beginning at 6 days[9]. In the present experiment, using locusts bred in this Department, from material kindly supplied 2 years ago by the Anti-Locust Research Centre, London, the pattern of response differed slightly from that reported earlier: slightly greater sensitivity was noted. The great heterogeneity of response of different individuals after the initial lag of several days[9] suggests a strong genetic element in the sensitivity to heat treatment and the slight differences in response noted probably reflect some genetic differences between the stocks used.

The individual sampled on the third day of treatment was found to possess a low mean chiasma frequency, but this was just within the normal control mean range (Fig. 1). In some cells, however, a measure of distal localization was found (Fig. 2) which indicated that the heat-treatment effect was just beginning to be shown. This was borne out on days 4 and 5, where both individuals sampled on each of these two days showed reductions in chiasma frequency, with some accompanying localization, which placed them well below the control mean range (Fig. 1; 3–7). Univalents were first found on day 5 (Fig. 5). As before, the most drastic initial reduction was found on day 6 (Fig. 1; 8–10). On subsequent days all individuals showed varying degrees of univalence.

On days 4 and 5, when appreciable reductions in chiasma frequency were found at diplotene and metaphase I, the autoradiographs showed that the latest labelled cells, which were involved in premeiotic DNA synthesis at the time that the treatment was begun, were still at zygotene. This first wave of labelled cells did not reach diplotene-metaphase I until the sixth day (Fig. 11), coinciding with the rapid drop in chiasma frequency previously established for this day. Although no label was found beyond zygotene on the fifth day, on the sixth day label was found over both chromatids at all stages of meiosis from pachytene—anaphase II in both of the individuals sampled. This shows that the period of premeiotic DNA synthesis in this species is no longer than 1 day at 40° C and also that leptotene and zygotene are of 5 days duration at 40° while all of the remaining meiotic stages from late pachytene to anaphase II are completed within 1 day at 40° C. No label at metaphase I or II was found on days 7 or 8, but another wave of labelled cells was found at these stages in the one individual taken on the ninth day. As only half the chromosomes were labelled in this individual at metaphase I, this must, on a semi-conservative model of chromosome replication, have been the third wave of labelled cells to pass into meiosis, corresponding to those cells which were undergoing DNA replication two spermatogonial mitoses before meiosis. The second wave of labelled cells must have passed through meiosis between the seventh and eighth days and been missed (Fig. 1). This would make the time of meiosis 6 days and the time of spermatogonial mitosis 1·5 days at 40° C.

More important than these considerations of meiotic timing is the observation that the reduction in chiasma frequency begins some 2 days before the labelled cells reach diplotene-metaphase I. This shows quite clearly that the events which are affected by the heat treatment and which lead to a reduction in chiasma frequency (which may coincide with the time of chiasma formation



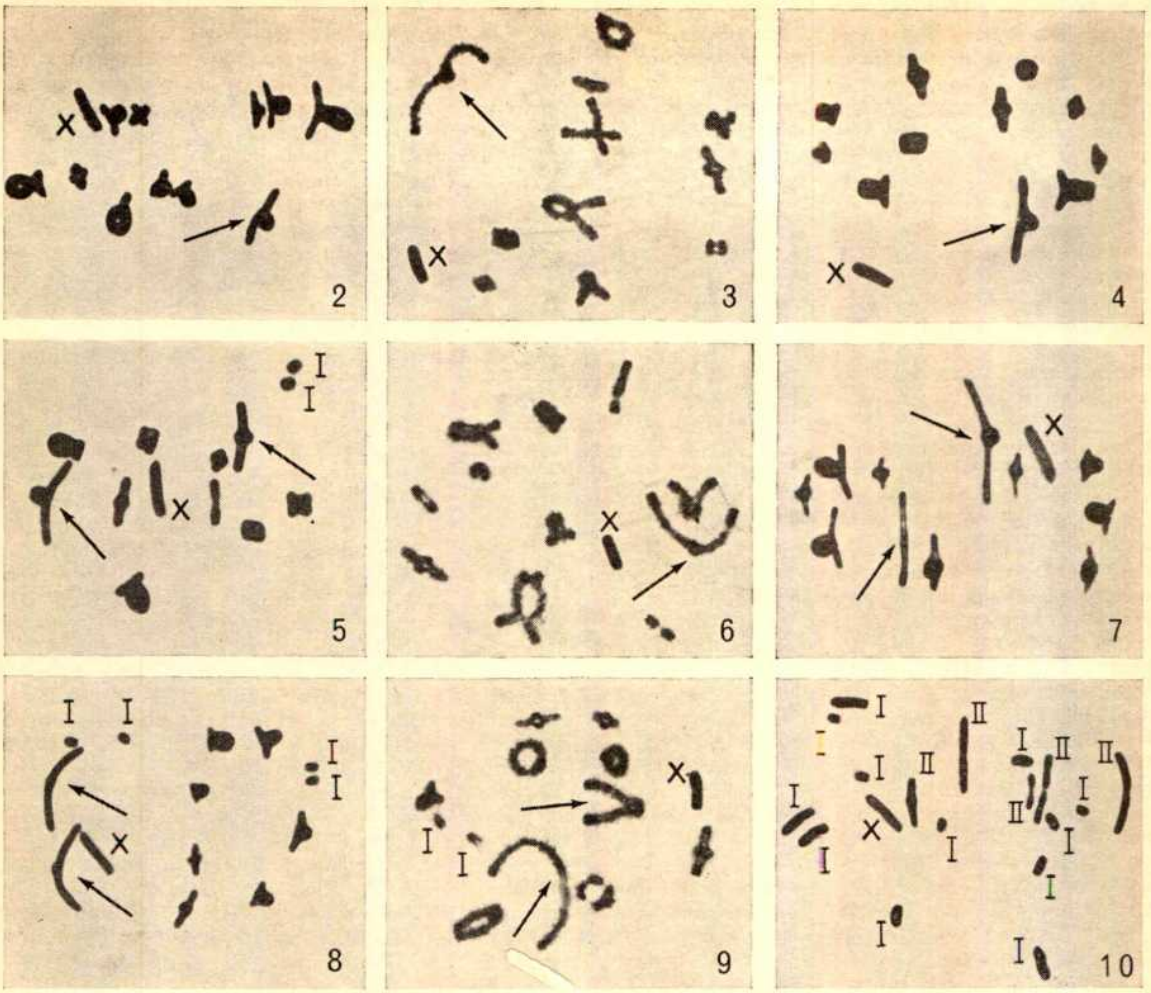


Fig. 1. Pattern of chiasma frequency reduction of labelled individuals of *S. gregaria* achieved at a constant 40° C. Means, standard deviations and (dotted) cell ranges are shown for each individual sampled. The first wave of labelled cells to reach metaphase I did so in both individuals on day 6 (*A*). The third wave arrived on day 9 (*C*). The second must have reached this stage between days 7 and 8 (*B*).

Figs. 2–10. Chiasma frequency reduction with accompanying localization observed at diplotene and metaphase I after 3–6 days at a constant 40° C. Fig. 2: 3 days heat treatment: atypical distal localization beginning. Figs. 3–4: 4 days heat treatment: slight chiasma frequency reduction with distal chiasma localization. Figs. 5–7: 5 days heat treatment: greater reduction with univalent formation beginning. Figs. 8–10: 6 days heat treatment: reduction, localization and univalence all well marked. (Figs. 2, 4, 5, 7, 8, 10: metaphase I, Figs. 3, 6, 9: diplotene.) (All × *c.* 900.)

or, more likely, precede it) do not occur at the time of premeiotic DNA synthesis but take place at least 2–3 days (at 40° C) after this period of DNA synthesis is complete. This places the time of chiasma formation in zygotene or early pachytene nuclei.

The second experiment carried out was the timing of meiosis at the "control" temperature of 30° C. Ten male locusts were injected with about 10 μc. of tritiated thymidine in saline, as before, and maintained in an incubator at a constant temperature of 30° C. One individual was taken each day on days 3, 8, 9, 10, 11, 12, 13, 14, 15, 16. On autoradiographs prepared as before and exposed for 40 days it was found that labelled cells reached diplotene—metaphase I on days 13 and 14. This shows that the premeiotic DNA synthetic period and the duration of the pachytene—anaphase II stages are both approximately 2 days at 30° C compared with 1 day at 40° C, while the total duration of meiosis is 14 days at 30° C, compared with 6 days at 40° C. This gives a Q_{10} for this temperature range of 2·3.

It was known from earlier experiments[11] that a heat-treatment of 2 days at 40° C could irreparably modify the chiasma properties of those cells which were at the sensitive stage of meiosis when the heat-treatment was applied and that if returned to a temperature of 30° C a pulse of cells showing reduced chiasma frequencies, with univalent formation, would pass through meiosis. Because

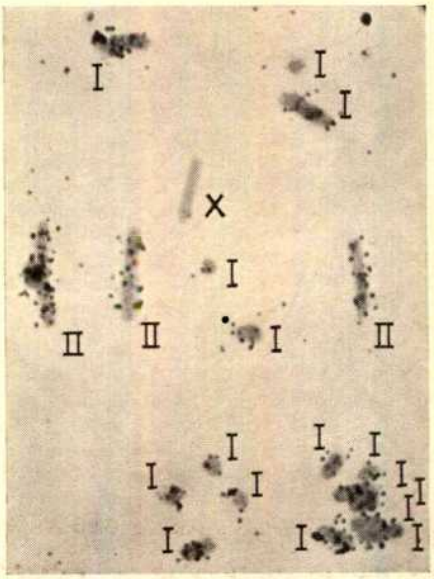

Fig. 11. Autoradiograph from one of the two individuals sampled on day 6 showing the arrival of tritiated thymidine-labelled chromosomes at metaphase I. 3 bivalents and 16 univalents are present in this cell. The late replicating Z chromosome is unlabelled. (× 1,800.)

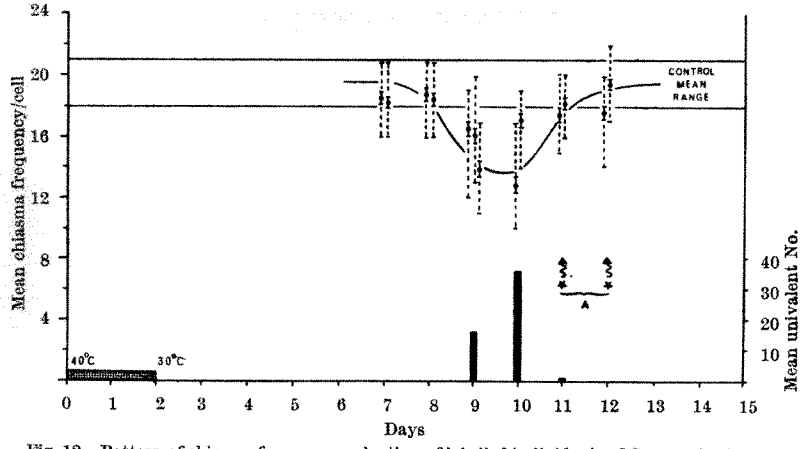

Fig. 12. Pattern of chiasma frequency reduction of labelled individuals of *S. gregaria* observed at 30° C after 2 days heat treatment at 40° C. Means, standard deviations and cell ranges again provided for each individual. One of the two individuals sampled on days 11 and 12 showed labelling in both chromatids at metaphase I and II (*A*). These cells were engaged in premeiotic DNA synthesis at the beginning of the heat treatment.

of the much slower rate of development at 30° C, however, these affected cells do not reach diplotene—metaphase I until a week or so after returning the locusts to this lower temperature. It was considered that this slower developmental rate found at 30° C might lead to a clearer separation of the time of premeiotic DNA synthesis from the time at which the high temperature treatment begins to affect chiasma formation. Accordingly, in the third labelling experiment, fourteen male locusts were injected, as before, with about 10 μc. of tritiated thymidine in saline and heat-treated at 40° C for 2 days. They were then transferred to an incubator maintained at 30° C and two locusts were dissected on days 7, 8, 10, 11 and 12; three were taken on day 9. One of the fourteen injected died. When autoradiographs were successfully developed (exposure time 60 days) chiasma frequencies were once again scored in twenty cells from the remainder of each testis, in propionic-orcein squash preparations, and standard deviations and means calculated. The results are shown in Fig. 12.

On days 7 and 8 both individuals sampled possessed low mean chiasma frequencies, but these were well within the normal control range. On the ninth and tenth days, however, marked reduction in chiasma frequency was evident, with accompanying univalent formation along with the tendency for the localization of those chiasmata which do form to the chromosome ends. On days 11 and 12, recovery was well under way, though it was by no means complete. It was found that the autoradiographic results confirmed and extended those obtained before. When chiasma formation was greatly reduced on days 9 and 10, the most advanced label was confined to zygotene nuclei. Labelled cells did not reach diplotene—metaphase I until days 11 and 12, when one of the two individuals taken on each of these two days showed labelling in all chromatids at metaphases I and II. The fact that both individuals on these days did not have identical labelling properties suggests that the wave of labelled cells passes through these later stages of meiosis within one day after this combined 40–30° C treatment, with a mean of about 11·5 days, and might be missed if only one individual is sampled per day.

The observation that the labelled cells do not reach metaphase I until days 11 and 12 shows that not only is the time of chiasma formation, or the time of some possibly synaptic stage preceding chiasma formation which is sensitive to heat treatment, not coincident with the time of premeiotic DNA synthesis, but it is sufficiently separated from this for a considerable heat-treatment effect to be manifest and recovery to be well advanced before the labelled cells pass through mid-meiosis. Clearly any hypothesis to explain chiasma formation, such as the copy-choice hypothesis, which involves the formation of chiasmata at the time of premeiotic DNA replication can no longer be entertained. Hypotheses which require chiasma formation to occur before the time of DNA synthesis[12] are even further from the truth. These findings are in agreement with the conclusions drawn by Lawrence, based on the effects of radiation on chiasma frequency[13,14] and recombination[15], that these take place after DNA synthesis is complete, during the more classical times of zygotene or pachytene.

While this work was in progress, two independent sets of observations of a comparable type, using genetic recombination rather than chiasma frequency, were published. In one[16], a 1 day heat-treatment of 35° C was given to *Drosophila melanogaster* females and the effect of this heat shock on recombination frequency determined on subsequent days at 25° C. As described above in *Schistocerca*, a wave of affected cells passed through meiosis giving a maximum effect in eggs laid on the ninth day. The effect itself differed in being an increase in crossing over adjacent to the centromere of chromosome II, though this may well reflect an overall decrease, with the tendency for proximal localization. The time taken for tritiated thymidine-labelled oocytes to mature was determined in autoradiographs of histological sections of ovaries. Because the mean time of oocyte maturation within the ovary was also 9 days, the authors came to the conclusion that recombination does occur at the same time as DNA synthesis. They did not determine the mean time of oviposition of labelled eggs, however, which is more relevant. To explain the discrepancy with our results on locusts, this need only be longer than the time of egg maturation within the ovary by 1 or 2 days. Alternatively, the time of the prophase (synaptic ?) stage sensitive to the heat treatment may, in this material, be separated from the time of DNA synthesis by an interval no greater than 1 day. In this case a 1 day sampling programme would lack the resolution necessary to separate these stages. In the second report of this type[17], recombination was measured in the liverwort *Sphaerocarpus donnellii*, subjected to a heat treatment of 35° C during the daytime. It was concluded that an effect of the heat treatment could be obtained after the fifteenth day post-fertilization, although DNA synthesis, as estimated by radiation-induced mutation studies, is completed by this time. These findings are thus in direct agreement with those obtained in *Schistocerca*.

One final observation which provides valuable support for the conclusions drawn above is that of Westergaard[18] using the Ascomycete fungus *Neotiella rutilans*. Here nuclear fusion of two haploid nuclei takes place immediately before meiosis in the ascus. Using Feulgen microspectrophotometry he has concluded that, in this species, DNA doubling appears to occur before nuclear fusion. In this instance, recombination between dissimilar genotypes could hardly occur at the time of DNA synthesis if, at this time, the two haploid nuclei have not yet fused.

These findings in *Schistocerca*, *Sphaerocarpus* and *Neotiella*, three completely different life forms, are sufficiently clear for us now to be able to say with certainty that chiasma formation and genetic recombination do not occur at the time of premeiotic DNA synthesis or earlier. In *Schistocerca*, chiasma formation must take place at least several days after premeiotic DNA synthesis is complete, during the classical time of zygotene or early pachytene and true breakage and reunion must be involved. Whether hybrid DNA formation[5] is also involved in this

exchange process will, perhaps, be one of the next things to attempt to decide.

STRUCTURE DEVELOPMENT IN AGGREGENS

By PROF. MERWIN MOSKOWITZ, DR. GRACE F. AMBORSKI and CAROLAN H. WIEKER

Department of Biological Sciences, Purdue University, Lafayette, Indiana

UNDER appropriate conditions, established strains of cultured mammalian cells aggregate[1] and with continued cultivation such aggregates grow in size and eventually fragment. The cycle is repeated as the individual fragments grow in size and fragment[2]. In a growing culture, cells which adhere to each other in a group taking the form of a relatively organized mass are referred to as "aggregens". In our initial studies the development of aggregens from three strains, *HEp*$_2$, *WISH*, and *L* strain was determined[2]. The aggregens of these strains varied both in external appearance and in internal organization. It was found, however, that in all cases there was a relatively thin peripheral layer of healthy cells and active multiplication occurred in this region, while the interior portion of the aggregens seemed to consist of deteriorating or dead cells. The cells in the outer layer did not appear to exhibit any definite structural features. As the growth of cells in the form of aggregens provided one of the requisites for structural differentiation, however, we thought that conditions might be found which would permit such differentiation to occur.

We have now been able to form aggregens from fourteen additional established strains of mammalian cells (Table 1). We used the same methods for aggregating cells[3] and culturing aggregens[2] as in our previous experiments. We observed that some of the strains formed structures and this article reports the details of our observations.

Cell strain: *Normal epithelial; † malignant epithelial; ‡ normal fibroblastic.

The development of structures was first noted in aggregens formed from cell strain *MK*$_2$. This strain has been studied more extensively than the others. Isolated from normal monkey kidney in 1955, it has been maintained in continuous cultivation since then[4]. In sections of aggregens of this strain (Fig. 1) transverse longitudinal sections of tubular structures were noted in the healthy outer portion. In addition to the presence of these it was noted that all the remaining cells in this region of the aggregen were arranged in various patterns and were not randomly orientated as they are in aggregens with amorphous layers[2]. Whereas the cells of the other strains required a number of days to aggregate, the cells of the *MK*$_2$ strain aggregated quite rapidly and complete aggregation of all the cells occurred within 24 h. When aggregation was carried out on the roller drum in a peptone medium containing β and γ globulin serum fractions, a number of aggregates formed in the tube. This medium was removed at the end of 24 h and a medium consisting of 10 per cent horse serum in Eagle's mixture was added. Shortly after, the smaller aggregates joined together to form a single large aggregate. When the initial aggregation procedure was carried out in the medium containing serum, a single large aggregate formed within 24 h.

In order to determine the time sequence for the development of structures in *MK*$_2$ aggregens, a large number of aggregates were made. They were fixed, sectioned, and stained immediately after aggregation had been observed. This process was repeated at daily intervals during the differentiation of the aggregates. The youngest aggregates did not exhibit any tubular structures but, although the arrangement of cells was essentially amorphous, there appeared to be grouping of cells within the aggregate. Structures did not develop in the aggregens until a certain size had been achieved, and degenerating and dead cells were observed to be present in the interior of the aggregen. With continued growth of the aggregen, the structures of the outer healthy layer were no longer observed and had an amorphous appearance as also did the cells in the outer layer of daughter aggregens that developed following the fragmentation of the parent aggregen. Aggregens apparently grow by the multiplication of cells in this healthy layer at the periphery, and when the outer layer reaches a certain size the cells on its inner border become ill and die probably as a result of the lack of nutrients available to them[2]. It would appear, therefore, that after the period in the growth of the aggregen during which structures develop, the next generation of cells are incapable of forming differentiated structures. Moreover, it would also seem that when the structures "arrive" at the inner border of the outer layer they are obliterated by the necrosis that occurs here.

Clone cultures were developed from the *MK*$_2$ cell strain using Puck's method[5] and aggregates were made with cells from the clone cultures. Structures similar to those noted in aggregens of the original *MK*$_2$ strain were observed to develop in aggregens of these clone cultures. Furthermore, the sequence of structure development was similar to that in both parent and daughter aggregens.

The structures observed in aggregens of other strains of cells were mainly in the form of vesicles (Fig. 2). The aggregens formed from one of the HeLa sublines (S_3) (Fig. 3) appeared to contain large numbers of adjacent

vesicles which resembled the organoid type of structure in tumours produced *in vivo* by this strain[6]. However, aggregens of another subline of HeLa (Gey) were amorphous. This variation, dependent on the subline of HeLa used, contrasted with the situation observed in HeLa and L strains; for here the aggregens produced from numerous clone cultures of both strains manifested no structural differences from those observed previously[2]. On the basis of their cellular organization, the aggregens that have been studied thus far can be divided into two general groups, "amorphous" and "structured". A distribution of the cell strains in these groups is given in Table 1. The types of organization which we describe here developed in our standard medium (10 per cent horse serum in Eagle's mixture). It is possible that, under different environmental conditions, or by the addition of different substances to the growth medium, differences in the organization of the cells of respective aggregens might have been observed. In preliminary experiments along these lines some differences in organization have been noted.

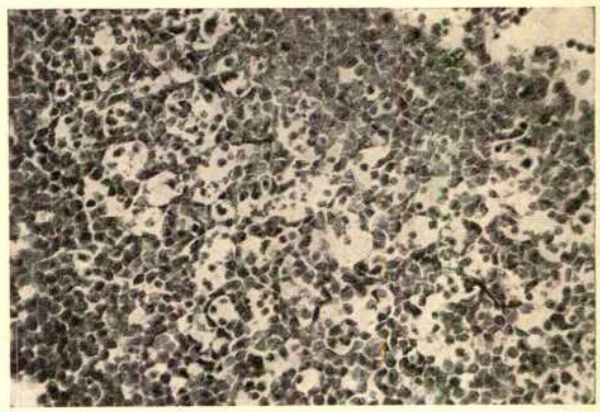

Fig. 3. Cross-section of outer layer of aggregen of HeLa S_3 strain (× 120).

Discussion. It was previously observed that, although cultured mammalian cells can aggregate, it takes from a few days to a week for this to occur[1,3]. With cells from chick embryos up to about 10 days of age, aggregation occurs relatively rapidly and is complete within 24 h. The ability of the cells to aggregate decreases as the embryo grows older, or if the embryonic cells are maintained as a monolayer[7]. Although they have been grown in culture for more than 10 years, cells of the MK_2 strain aggregate in the same manner as do cells taken from young embryos; that is, in a serum containing medium they form a single large aggregate within 24 h. In view of the fact that they can form definite structures, it would seem likely that the cells of this particular strain of cultured cells are endowed with some of the unique properties of cells present in young embryos.

The development of structures in aggregens of this strain appears to occur at a particular time in their cycle of growth as aggregens. Their potential for producing the structures is not apparently expressed until the cells have interacted for a certain time. The cessation of structure development with increasing age of the aggregens suggests that continued association of cells in the tissue-like mass finally results in the repression of the ability to form these structures. The sequence of events can be likened to embryonic development in which a particular type of differentiation occurs at a given period in the growth of the embryo and then ceases.

It is evident that the production of structures does not result from the interaction and sorting out of different types of cells in the original culture because structure

development occurred in clone cultures derived from the parent MK_2 strain. Although it cannot be said that the ability to form structures still resides in every cell of the original strain, clearly the potential to form these structures is present. The structures observed in MK_2 aggregens often exhibited a definite tubular shape; however, there was great variety both in the size and conformation of the tubules. During cytodifferentiation of the embryo the development of specific structures is assisted by the structures already present. These provide support and may also act as guides to groups of differentiating cells. It may therefore be possible to produce more definite and regular development of structures if aggregens are produced from mixtures of the MK_2 strain and another strain of cells, with the latter strain providing some form of support or matrix for the MK_2 cells. The observation that the organization in the aggregens produced with a tumour cell strain, HeLa S_3, is similar to structures observed in these tumours grown *in vivo* lends support to the previous suggestion that the properties of these cells in aggregens may resemble those of natural tumours[2]. No variations in the structure of the aggregens derived from clones of the HEp_2 and L strains of cells were observed. The differences which we noted in structure development using different strains of HeLa cells may reflect a greater variability among cells in cultures of the latter strain than in those of the other two. Without any doubt, the ability to form structures is associated with a surface property of cells. Yamada[8] has observed that HeLa cells form different types of clones; for example, tight clones and loosely packed clones[8]. The various properties of the surface of cells, as manifested by the type of clones that form, may be related to their ability to develop structures when grown as aggregens.

PRECIPITATION OF TOBACCO MOSAIC VIRUS BY MACROMOLECULES: A METHOD FOR ESTIMATING MOLECULAR VOLUMES

By DR. W. F. DUDMAN
C.S.I.R.O. Division of Plant Industry, Canberra, Australia

TOBACCO mosaic virus (TMV) diffuses through agar gels[1] but not through gelatine gels[2]. To investigate the cause of this unexpected anomaly the behaviour of TMV in solutions of gelatine and agar was investigated. It was established that the virus is precipitated by solutions of gelatine and agar above specific threshold concentrations. The addition of TMV to solutions containing the threshold concentration, or more, of gelatine or agar leads to the immediate formation of a visible precipitate. No visible reaction is detected below the threshold concentration.

The present article is concerned with the use of this type of precipitation reaction between TMV and macromolecules as a simple and rapid means of estimating the volume displaced by the macromolecules.

The mechanism by which TMV is precipitated is thought to be one of incompatibility and mutual spatial exclusion between the virus and macromolecules, that is, another manifestation of the phenomenon described in its various aspects by Albertsson[3], Ogston and Phelps[4], Laurent and Ogston[5] and Laurent[6]. When a large enough quantity of the macromolecular material has been added to confine the virus in a volume sufficiently small for the distance between the central long axes of the particles to be of the order of 200–250 Å, the particles aggregate and form needle-like crystals[7]. Taking the TMV particle to be a rod with a length of 3,000 Å and diameter of 150 Å, and a molecular weight of 40 million (ref. 8), it can be calculated that 1 mg of TMV contains $1{\cdot}5 \times 10^{13}$ particles and that these occupy 0·009567 ml. when the interparticle spacing is 250 Å.

Because of the tendency of TMV particles to distribute themselves so as to occupy all the available space as uniformly as possible[7], it is reasonable to postulate that in a mixture of TMV and a macromolecular species all the space not occupied by the macromolecules must be occupied by TMV, and vice versa. Thus when a macromolecular species is added step by step to a suspension of TMV, the virus particles are thought to occupy a progressively smaller fraction of the volume of the solution, with a progressively smaller distance between particles, until at the threshold concentration the TMV particles are less than 250 Å apart and they aggregate. This threshold concentration of macromolecules is thus the concentration required just to fill or to occupy all the remaining space in the solution. From an estimate of this remaining volume, obtained by subtracting the volume occupied by the TMV from the total volume, it is possible to calculate the volume occupied by a single macromolecule by using the molecular weight of the macromolecules and Avogadro's number ($6{\cdot}023 \times 10^{23}$ molecules per gram molecular weight) (ref. 9). This in turn can be used to obtain the dimensions of an equivalent sphere.

The validity of this hypothesis and its applicability as a general method for estimating molecular volumes were tested by observing the precipitation of TMV by a range of compounds, the molecular dimensions of some of which have already been investigated by other methods.

The following macromolecular materials were used: agar ('Ionagar No. 2', Oxoid), bovine serum albumin (Armour), casein (light, white, soluble, British Drug Houses), dextran 2,000 (Pharmacia), dextran grades *A* and *C* (British Drug Houses), gelatine (fine leaf *E*, Société d'Exploitation des Produits Chimiques Coignet), hyaluronic acid (ox synovial, kindly provided by Prof. A. G. Ogston), and *Rhizobium meliloti* strain *F* polysaccharide[10].

The procedure used for the precipitation was simple. Where sufficient material was available, samples were dissolved in a phosphate buffer[11] and various dilutions made. With gelatine the reaction was carried out with 1 ml. volumes in small tubes, and with all the other materials in 3 ml. volumes in 1 cm cuvettes. Small samples of TMV were added to the solutions and thoroughly mixed. The gelatine experiments were carried out with the addition of 0·03 ml. containing 0·63 mg of TMV, and the experiments with other materials with the addition of 0·04 ml. containing 2·4 mg of TMV. The

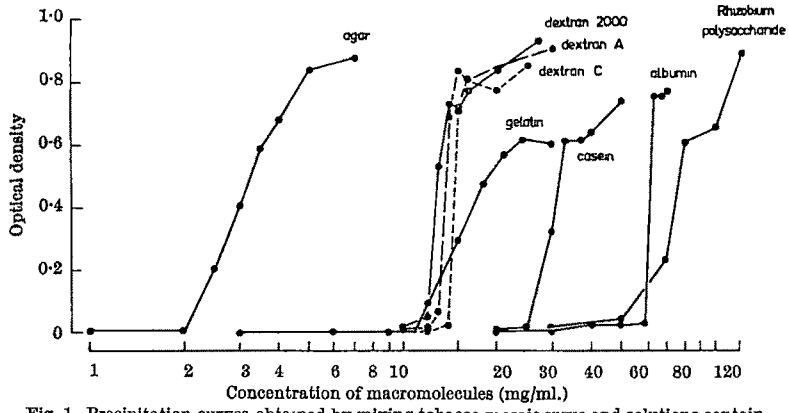

Fig. 1. Precipitation curves obtained by mixing tobacco mosaic virus and solutions containing various concentrations of macromolecular materials. Optical density measurements were made 30 min after mixing.

mixtures were allowed to stand for 30 min at room temperature, except agar, where incubation at 45° C was used to prevent the formation of a gel. The optical density of the mixtures was determined at 750 mμ. It was found necessary to make this measurement without agitation of the tubes or cuvettes in order to avoid temporary changes in optical density. When the turbid suspensions were shaken the optical density rapidly decreased by about 20 per cent but returned to its former value within a few minutes when left stationary. For this reason the mixtures were always made directly in the vessels in which the optical density readings were to be made.

In order to minimize the weight of material required when using bovine serum albumin, a direct titration procedure was utilized instead of the series of dilutions. Small volumes of a concentrated albumin solution (150 mg/ml.) were added to 1·5 ml. of TMV suspension in a cuvette. After each addition the solution was mixed and allowed to stand for 15 min before the optical density was determined and more albumin added. When the mixture was turbid the end-point was sharply defined.

The results obtained by these procedures are shown in Fig. 1. The shapes of the curves for all the macromolecules were the same: below a certain threshold concentration, characteristic for the material, there was no precipitation, but above the threshold concentration the optical density of the mixture rapidly increased with increased concentration until a maximum density was reached.

Examination of the precipitates by light microscopy showed needle like crystals of the type described by Cohen[12], except in the case of hyaluronic acid where tactoids[7] were observed. A precipitation curve was not obtained with hyaluronic acid because this material was not available in a sufficiently concentrated form for dilutions to be made. The threshold concentration for hyaluronic acid was taken to be 4·4 mg/ml. because this was the only concentration at which turbidity was obtained when TMV was added, and this was the highest concentration of hyaluronic acid available.

The following points (all obtained from unpublished data) are considered to support the view that the mechanism of precipitation is one of mutual incompatibility between the virus and added macromolecules, which results in compression of the virus into smaller fractions of the solution until phase separation in the form of crystallization or the formation of tactoids occurs. (1) Electron micrographs of the precipitated material show closely packed arrays of parallel rods, indicating that the precipitates contain only TMV. (2) The amount of precipitation is directly proportional to the amount of virus present in the mixture and is independent of the macromolecular material provided sufficient is present to exceed the threshold concentration. (3) When a sufficient amount of macromolecules has been added to achieve maximum turbidity and the mixtures are centrifuged at low speed (11,150*g* for 15 min) no virus remains in the supernatant liquid. Thus all the virus is aggregated and none is left in the volume of the mixture occupied by the macromolecules. (4) The threshold concentrations found here for dextrans (12·5–14·5 mg/ml., depending on molecular weight) are similar to the concentration (14 mg/ml.) at which the sedimentation behaviour of dextrans was found by Ogston and Woods[13] to show a change. These authors interpreted this as resulting from the fact that the dextran molecules are no longer separate and discrete, that is, this is the minimum concentration of dextran required for the molecules just to fill all the available space.

Table 1. MOLECULAR VOLUMES AND RADII OF EQUIVALENT SPHERES CALCULATED FROM MACROMOLECULAR THRESHOLD CONCENTRATIONS REQUIRED TO PRECIPITATE TOBACCO MOSAIC VIRUS

Macromolecular substance	Molecular weight	Threshold concentration (mg/ml.)	Concentration of molecules at threshold (No./ml.)	Unit volume per molecule (Å³)	Radius of equivalent sphere (Å)	Molecular shape and dimensions reported *in lit.*
(*a*) Results obtained in reactions with 0·80 mg TMV/ml. Volume occupied by TMV at threshold: 0·00765 ml./ml.						
Agar	160,000	2·04	$7·69 \times 10^{15}$	129×10^6	313	Not available
Albumin	69,000	63·5	554×10^{15}	$1·79 \times 10^6$	75	Almost spherical, major axis 144–150 Å (ref. 14)
Casein	16,300	25	924×10^{15}	$1·07 \times 10^6$	64	Rod, length 150 Å, radius 8 Å (ref. 15)
Dextran 2,000	2,000,000	12·5	$3·76 \times 10^{15}$	264×10^6	398	Not available
Dextran *A*	200,000	13·5	$40·7 \times 10^{15}$	$24·4 \times 10^6$	180	Not available
	~275,000		$29·6 \times 10^{15}$	$33·5 \times 10^6$	200	
Dextran *C*	60,000	14·5	145×10^{15}	$6·84 \times 10^6$	118	Not available
	~90,000		$97·0 \times 10^{15}$	$10·2 \times 10^6$	135	
Rhizobium polysaccharide	8,000	57·5	$4,328 \times 10^{15}$	$0·229 \times 10^6$	38	Not available
(*b*) Result obtained in reaction with 0·63 mg TMV/ml. Volume occupied by TMV at threshold: 0·00603 ml./ml.						
Gelatine	90,000	11	$73·4 \times 10^{15}$	$13·5 \times 10^6$	148	Spherical random coil (ϱ_σ = 165–175 Å) (ref. 16)
(*c*) Result obtained in reaction with 1·6 mg TMV/ml. Volume occupied by TMV at threshold: 0·0153 ml./ml.						
Hyaluronic acid	13,000,000	4·4	$0·204 \times 10^{15}$	$4,825 \times 10^6$	1,048	Almost spherical random coil (ϱ_σ = 2,300 Å)

The results obtained for the molecular volumes, calculated from the threshold values shown in Fig. 1, are presented in Table 1. It will be seen that the molecular dimensions, expressed arbitrarily as radii of equivalent spheres, are of the same order as the published data where these are available.

Some of the results require comment. Little seems to be known of the molecular dimensions of agar. The value found here applies only to agar solutions. When turbid agar–TMV mixtures are allowed to gel the turbidity disappears within 15–30 min, showing that the TMV particles are no longer confined to a small volume. Agar molecules in the gel state thus appear to occupy less volume than when in solution.

The result for albumin (diameter of equivalent sphere 150 Å) is close to the dimension of the major axis of the prolate ellipsoid (150 Å) reported by Oncley, Scatchard and Brown[17] and the later prismatic molecule with dimensions 144 × 45 × 22 Å (ref. 14). However, other recent estimates of the albumin molecule by gel filtration in dextran[18] and diffusion through agar[19] give values of

BRITISH ASSOCIATION SUPPLEMENT—NOTTINGHAM, 1966

WHICH WAY TO CHANGE?

AN organization which goes back to the Great Reform Bill, which served as a learned society of the most vigorous kind through most of the nineteenth century, and which has retained a good deal of its original homespun independence, cannot fail to command respect and even affection. This is one of the reasons why it is good to see, with another revolution of the calendar, that the British Association for the Advancement of Science is still alive, that its programme is packed with the names of interesting people, and that the crowds will flock to Nottingham for the meeting in spite of the change in the timing of the summer public holiday in Britain. So much is common ground.

These days, however, each recurrence of the annual meeting of the association is also a time for asking what purpose is really served by the meeting and, for that matter, by the association as a whole. One difficulty is that the annual meeting has been overtaken by events, and particularly by the increasing speed with which news of discovery spreads within the scientific profession and beyond by means which are faster than annual gatherings can hope to be. Another is that science as a whole has become less accessible to the interested layman, although this is too frequently exaggerated. The immediate result, however, is that the British Association, in the annual meeting and in its less obvious work, has become less and less concerned with the advancement of science as such, and more and more of a popularizer, propagandist and proselytizer. Nobody complains at this change, which is at once desirable and inevitable.

Why then the talk of crisis? The annual report for the financial year to March 31 is a gloomy document. The association has been dipping into its meagre reserves, so that its Victorian sponsors must be turning in their graves. Revenues have risen buoyantly in the past decade, but costs have outstripped them. One result is that, in spite of the stringent economies, there is likely also to be a deficit in the year ahead. Another is that the association has taken to complaining, somewhat more querulously than may everywhere seem justifiable, that the Department of Education and Science should pay a larger share towards the educational work now being undertaken. Nevertheless, even though this is not a good time for fund raisers in Britain, the association and those outside who wish it well should not refrain from hoping for the comparatively little luck that could banish anxiety for a year or two to come.

In the long run, however, survival will require more than mere luck, which is why it is good to learn that the council of the association is now looking carefully at its motives for continuing to exist. Everybody will wish the council well. It is to be hoped that it will be as courageous and as imaginative as were the old people who first recognized the vacant place in British life for a scientific society which could turn its energies to evangelism and tub-thumping when circumstances required. There are two sorts of remedies that the council should be looking for.

In the first place, the annual meeting should be given a much firmer impact on the outside world. At present, of course, great crowds of people derive great pleasure from it, and will continue to do so in the years ahead. But the council is also right to recognize that the annual meeting is the focal point for the rest of its work throughout the year. As such, it deserves to be more exciting and more stimulating.

This year, at Nottingham, the association has taken a tiny step in this direction by arranging three symposia, outside the usual framework of the meeting, concerned with separate issues of public importance. The promise of the kind of discussion which might help to resolve public doubt has not, unfortunately, materialized. All but one of the speakers advertised for the symposium on supersonic aircraft, for example, belong to organizations committed to their development. Only Sir William Hildred, from the International Air Transport Authority, is in a position to be sceptical about their value without being actively disloyal to his employer. There is no sign on the programme of the man from the Noise Abatement Society, or of the taxpayer who may well consider that

This year's meeting of the British Association for the Advancement of Science is the fourth to have been held in Nottingham. The pages which follow include extracts from the Presidential Address in 1966 and some historical material, compiled by the editorial staff of *Nature*, which may help readers to appreciate how the British Association has changed over the years.

a nation which finds it hard to make ends meet should now squander £200 million, and a large part of its tiny skilled labour force as well, on such a risky venture.

If the British Association really wishes to make a mark on issues like these—and there is every reason why it should—then it must take a leaf out of the old books, and appoint committees to take up these important causes, see that intelligent reports on them are fully discussed in public, and then commit to them such prestige as it can command. There is a host of issues to be taken up. Such a course would often bring the association up against official doctrines, but it used not to be afraid of that. Perhaps the greatest of its present troubles is that it has been overtaken by gentility.

The money troubles are subsidiary but dependent. They would vanish overnight if the association abandoned its lecture services and some of its other novel undertakings. So why not then abandon them? This may seem a cruel question when there is undoubted evidence of sound achievement in the recent past, but it should not be dismissed lightly. Everything depends on what kind of organization the association wishes to become. If it sees itself as providing a continuing educational service of a special kind, handling large sums of public money and similar sums from industry and charity as well, then there will be a whole sequence of general treasurers going grey before their time. There should be some way of organizing these educational activities so that they finance themselves. If the lectures, for example, are as much appreciated as the association says, then local education authorities should be easily persuaded to pay more towards them. If, on the other hand, 3*s*. 9*d*. is more than the market is prepared to pay for providing a child with a single lecture, it is better to learn that now and not later. With the alternative methods of communicating science to young people, the association should not be surprised that the Department of Education and Science should be reluctant to increase its grant.

All this suggests that the association would be very much happier, and more fully in control of its own affairs, if it came to think of itself as what it used to be—an initiator of new projects, a catalyst of new ideas and a defender of those which are old and cherished. It should be ready to show other organizations how good works may be accomplished, but chary of undertaking too much on its own account. Most of all, it should beware of too much dependence on government departments. The arrangement with the Ministry of Technology by which the association has undertaken to encourage an interest in technical matters among young people is particularly suspect, for it is hard to know precisely how it will be able to earn its keep. And in the long run, of course, the objective should be to find some way of bringing forward from within itself a flow of new and vigorous ideas. There is every reason to believe that such activity would be at least as welcome now as it used to be. It would also be fun, which is not a negligible consideration.

INFORMATION

How best to manage scientific information? Section X of the British Association has had the wit this year to arrange a discussion on this important problem. More than that, it has had the good luck to recruit as speakers people who live with the problem every day —the Director of the National Lending Library, the Head of the Information Division at the National Science Foundation, and a representative from Aslib. Sir James Cook, the Vice-Chancellor of the University of Exeter, is devoting his presidential address to the same cause. No doubt the room in which the section will be meeting will echo for days with the sound of that evocative phrase "the information explosion". But what really is the problem?

In the first place, there are mechanical issues which have thrust themselves on public attention. The development of devices which simplify the reproduction of printed text has opened up the possibility of unfamiliar means of circulating information. Some people suggest that the most familiar means of communication between people—the printed page—may instead be replaced by an electrical connexion to some central bank of computers, and there is even talk of transferring to the machines not merely the task of storing information, but also the more subtle tasks of digestion and criticism. The first thing to be recognized is that the obvious advantages of speed and comprehensiveness which possibilities like this can offer are accompanied by certain risks. In particular, there is a danger that the machines, which are necessarily better at storing facts than ideas, may oversimplify the traffic in scientific information, and may neglect that function of the scientific literature which is to stimulate as well as to inform. There is also a real danger that some schemes intended to make the circulation of the scientific literature more efficient would, in reality, help to put it out of business. Those who make machines are as aware of these risks as the potential users, but that is not enough!

How to handle the scientific information is, however, comparatively easily decided. There remains the nasty suspicion that all the improvements of efficiency which the machines now seem to offer may merely enable a much greater volume of scientific information to saturate and overwhelm potential users. So many working scientists complain of the problems of assimilating information, and of distinguishing archival material from that which is intended to stimulate further work, that the nature of the scientific literature probably requires careful study. In other words, there is a need to attend to the quality of the literature as well as to its handling. At the very least, there is a need that it should become more pithy, more intelligible, and more effective as a means of intellectual communication within the growing profession of science. As things stand, there are plenty of suggestions for managing the computing machinery more effectively; improving the quality of the literature is unfortunately more difficult.

LAND AND HUMAN POPULATION

The following are extracts from the Presidential Address delivered on August 31, 1966, at the Nottingham Meeting of the British Association, by Sir Joseph Hutchinson, Drapers' Professor of Agriculture, University of Cambridge.

THE characteristic of our age is the dominance we have achieved over our environment. We can organize ourselves so that, according to Burton and Wibberley[1], "The six English conurbations of London, the West Midlands, south-east Lancashire, west Yorkshire, Merseyside and Tyneside, contain 17 million people at an average density of 8,050 persons per square mile", and we can establish a camp at the South Pole where men can live in reasonable comfort for months at a time, and maintain contact with the rest of the world. We can feed ourselves better than ever before. There are black spots in the food situation, but the chance of a man dying of starvation anywhere in the world is less now than it ever has been hitherto. We have even acquired the skill to escape from this Earth and to begin the exploration of space.

There is therefore a wealth of scientific achievement, but I believe it is important to temper any account of our successes by drawing to your attention what I believe to be our most serious failure. We can, with our present knowledge, feed, clothe and equip a larger human population than ever before, but a large and increasing share of our productive effort is absorbed in providing for further population increase and, despite our successful conquest of practically the whole of the plant and animal kingdom, we have not yet begun seriously to undertake the control of our own species.

Biologically, this is not a difficult undertaking. Even without modern knowledge and techniques, there have been periods in the past when our numbers in Britain were static, or even declined. The relation during the past millennium between population increase and prosperity has been discussed by van Bath[2], and he has drawn attention to the manifold interactions between the size of harvest and opportunities for industrial employment on the one hand, and nutritional level, age at marriage, and the incidence of epidemics on the other. Van Bath was concerned with a period ending in A.D. 1850, but we need to go no further back than the 1930's, within the experience of many of us here, to note a time when the birth rate was inadequate for replacement. So population increase is not inevitable.

Our difficulties in population control are social and emotional. In Britain we have not yet really accepted that population pressure is an immediate concern of our own, and not just a vague menace in distant parts of Asia. We forget that, in the United Kingdom, there are 570 of us to the square mile, whereas in India there are only about 385 (ref. 3). Western Europe is one of the most densely populated areas on Earth. Whether this amounts to over-population is, of course, another matter. I believe that Britain is in fact over-populated now, and will inevitably be more heavily over-populated in the future, whatever we may decide to do about it. Over-population means, in simple terms, too many people for the resources in land that are available to them. Recently there has been an important step forward in the definition and estimation of over-population. William Allan in his very valuable book *The African Husbandman*[4] has developed the concept of "Critical Population Density", the maximum population density that can be supported by a given agricultural system without progressive deterioration of the land. Allan was concerned with subsistence farming in a purely agricultural community, but the concept can be usefully applied much more widely than this. It is a characteristic of our biological environment that we can for a limited period exploit it in excess of its real productive capacity, and only after a lapse of time is it apparent that we have initiated in it a progressive decline. We have spent working capital as well as income, and when the capital has been depleted the income falls. This is easy to see in African shifting cultivation, when a reduction in the period of the recuperative fallow leads to degenerative changes in the natural vegetative cover, accelerated erosion of the soil, and declining yields in the cropping period. That the degeneration of the environment is a real problem, and may, and indeed does, lead to an almost irreversible decline in productivity, is evident from the present state of the Mediterranean lands after six or so millennia of overcutting, overgrazing, and overcultivation, and from the present state of heaths and moors in Britain for which we have the evidence of pollen diagrams that they once carried a forest cover[5]. One is reminded of the forester's bitter comment on so much of the agricultural development of Latin America—"Cut down wealth to sow poverty!".

This concept of "Critical Population Density" is relevant in all human communities. It is in the natural course of events that a developing community should service its development first by bringing into use its unused resources. There comes a time, however, when all the readily available resources have been brought in. At this point of time, the population density has reached the critical level, and the choices before the community lie between the over-exploitation of resources to the long-term detriment of the system, the planning of new systems of resource use that are both more conservative of resources and more productive of real income, and population control.

The history of population growth and the agricultural exploitation of the land in Britain is one of alternation between the first two of these choices, culminating in the position we have reached in the last decade, of an abundance of farm produce, even though the growth of our population continues unchecked. Our present food supply position might lead us to the complacent conclusion that we have now learnt how to match with increasing supplies our ever-increasing needs. The historical evidence is against such a conclusion, and current assessments of our need for, and use of, our limited land indicate that our present abundance may not be long continued.

Developing countries have in common a heavy dependence on agriculture, and agricultural systems that are still in the main exploitive. They differ substantially among themselves in the extent to which there is pressure of population on land, and in the nature and the degree of sophistication of the relationship between town and country. In all of them, the great need is for the initiation of agricultural revolutions of the kind through which Britain has passed. Having so recently been ourselves

through the fertilizer and mechanization revolution, we have been disposed uncritically to advocate fertilizers and machines for other countries. This was not the way that we emerged from exploitive to improving agriculture, and we have good evidence that these agents of our latest revolution are most successful where land is held on modern systems of tenure, and where the art of husbandry has already assimilated the practices of fertility conservation.

In India we know that the improvement of fertility is possible. We can see it in the highly fertile fields in the immediate vicinity of the villages. We know also that yield increases are obtainable from fertilizers. The agents of agricultural improvement work as they do in Europe. But the change in habits and customs necessary to establish the systematic conservation and distribution of the elements of fertility has hardly begun, and social inertia is such that land reform is extremely slow. Agriculture is static, and we are more in need of incentives than of knowledge, if change is to come about.

When European agriculture stagnated, some stimulus from outside the industry was necessary before a new phase of improvement began. It was the food shortages of the war-time blockade that set going the application of industry to agriculture in recent years. There is now a stimulus to Indian agriculture that could be used to initiate agricultural change if there is the imagination and determination to see it through. India is engaged on a great extension of water conservation and irrigation, often in multipurpose schemes involving power generation and industrial development. Here are opportunities to get agriculture moving, by undertaking land reform, transferring some surplus population from the land to industry, and providing the education and advice on the new farming practices necessary to ensure the conservation of the elements of fertility. In India the sequence of improvement must start with the mitigation of climatic risk, but then it should follow the pattern of this country —land reform, fertility conservation, and then fertility improvement. I only lived four years in India. I left with an unfulfilled ambition—to see whether, using both fertility conservation techniques and fertilizers, one could achieve in twenty years the level of fertility built up over 2,000 years on the village perimeter. I believe we know enough to set about such an enterprise, and, since that would mean multiplying productivity by two or three, the impact of such an achievement on India's food problems would be very large indeed.

African problems are of a different kind. There are vast areas where the rainfall is good and reasonably reliable, and the population small. But over most of them the soils are very ancient, and have been leached to the poverty line. Even in Uganda, where the climate is good and the soils better than the African average, fertility levels are not such as to sustain a high level of production. As land is abundant, it has been impossible to maintain growth in agricultural production over half a century, and in particular there has been a great increase in production for export. Little has been achieved in improving the productivity of the land, but the need for greater productivity has not been apparent while production could readily be increased by bringing more land into cultivation. Pressure on the land is still not great, but pressure on the market for export crops is increasing. It is quite clear that the increase in national income to which Uganda aspires cannot be financed by increases in the exports of cotton and coffee. But unless agriculture can contribute substantially, the increase in national income will be slow. Here also we can learn from western European experience. Buganda, the central area of Uganda, gained through the mailo system of freehold in land, the advantages Britain gained from the enclosure movement. The next stage in British agricultural progress stemmed from the example of high farming in the Netherlands, where the stimulus of town demand led to the development of intensive farming. In Uganda there is substantial urban development that has already had a great impact on the farming up to 20 miles or more from the town boundaries. Milk is produced in quantity and retailed in the towns by men who take it in on bicycles. The staple foodstuffs are taken into the town markets on bicycles and lorries. Traditional cash crops are of little importance near the towns, but the food crops are fully integrated into the cash economy. This is the new growing point of Uganda agriculture, as food and industrial crops provided the growing point of the agriculture of the Netherlands. What is now needed is the drive and imagination to initiate a new system of farming where livestock products and food crops have a ready sale, and where the conservation of fertility that can be practised with mixed farming can be developed, and supplemented by utilization of town wastes and fertilizers. Uganda agriculture could traverse in two decades the trail opened up over two centuries by the agriculture of western Europe.

It will be apparent that I advocate for both India and Africa a pattern of agriculture that many advanced practitioners of British agriculture are giving up. The conservation of fertility means the conservation and distribution of bulky organic manures, and this is an expensive matter where labour costs are high. But we are considering developing economies where labour costs are low, and where fertilizers have to be bought with the proceeds of the sale of low-value agricultural produce. A poor country, hoisting itself up on its own resources, must use first the local materials and the home labour force. This is the way we started on the improvement of our own land and, even if it could be demonstrated that the whole process could be successfully carried out with inorganic fertilizers, it would still remain true that only by making the most of local materials, and using local labour, has a poor country any hope of escape from exploitive agriculture. Only the rich can afford to squander organic manures. But this is not all. Western European mixed farming revolutionized the nourishment of our people as well as the nutrition of our soils, and its establishment in developing countries would be the surest way of ensuring a high dietary standard for the human population.

Let me be quite clear. In advocating the sequence of change and improvement through which western Europe has achieved high agricultural productivity, I am not suggesting that the products of industry should be eschewed until the practices of the Norfolk improvers have been applied. The successive revolutions through which we have passed can—and should—be telescoped. I do not believe that their order can be reversed.

Let us now look to the future. The lands that remain untilled are agriculturally unpromising, and in any case are likely to be wanted to meet the needs of growing local populations. The security of Britain's food supply depends on the continued improvement of the productivity of the lands, here and overseas, that we now farm. That there is a real prospect of this continued improvement, we can be assured. Exploitive agriculture has given way to conservation and improvement in all the advanced communities of the temperate parts of the world. But other needs and other problems face us, with our limited land resources and our large and increasing population. Of these, the most important are water supply and effluent disposal, and recreation. Britain is well watered. Our rivers run the year round, and we have great underground aquifers on which we have been accustomed to draw. But a population of 50 millions, living as we do, and running vast industries that use prodigious quantities of water, is now drawing on our supplies at a rate that will soon exceed summer availability. Moreover, we all too easily overlook the fact that our rivers are not only the source of most of our domestic and industrial water. They are the only possible recipients of our domestic and industrial effluent, with all the pollution that that entails. Here we must distinguish between organic and industrial pollution. Given a summer flow adequate to dilute sewage effluent, organic pollution

is dissipated by water life, and rivers contaminated with sewage become fresh and sweet by natural means. Industrial pollution is another matter. We have learnt a lesson with insecticides. Persistent poisons turn up persistently in unexpected places, and they are cumulative. The most persistent of all water contaminants are industrial wastes, containing indestructible matter such as metal salts. Water so polluted must run to the sea. We are getting pollution conscious, and control of effluent discharges is much better than it was, but we still have much to learn, and we still need to develop the kind of public conscience that will make the proper disposal of effluents a matter of civilized behaviour rather than of law enforcement. Indeed we still have to get our own thinking straight on our handling of persistent materials.

Water supply and effluent disposal must be planned together. Of water we have enough, but it is going to cost us a great deal to keep it pure, and to ensure that we have enough all the year round. Deforestation and drainage have increased the amplitude of seasonal fluctuations. Agricultural demand for irrigation is increasing where supplies are most limited, and at the time of year when they are at their lowest. We must store our winter surplus, and there are only two methods of storage, in surface reservoirs and in the aquifers from which we pump a part of our supplies. Surface reservoirs submerge land, much of it good agricultural land, some of it with vegetation of great natural and scientific interest, and some of it of great recreational value. But storage we must have, and we must site it where it will do least damage. Storage in estuaries may help, but the maintenance of flow to keep our rivers from degenerating into open sewers will alone require substantial up-river storage. Recharge of aquifers we have only recently begun to take seriously, but we have some limited experience and we urgently need more extensive experimentation.

Recreation and amenity also make demands on our limited land. The countryman has recreation and amenity on his doorstep, and his holidays are in consequence much less important in his life than are those of the townsman. Most of us live in towns now, very many of us in vast conurbations from which escape is expensive and time-consuming. If we have a semi-rural home, it is at the expense of our family life, since one member of the family is out of the house from dawn to dusk, five days a week. So we get the great summer exodus to the country and the sea, the growing demand for rural cottages as weekend retreats for those who can afford two homes, and the great increase in fishing, sailing, mountaineering and—remarkably!—caving. This is the relief we seek from the stress of urban life, and in our consideration of the use of our land, we must take it increasingly into account. Indeed, already our resources near the great cities are under strain.

Away from the industrial regions there are great areas suited to recreational use, though they are less accessible to those who need them most. Wales, and large parts of Scotland, could profitably provide recreation for many more than now enjoy them. Here is an opportunity in land use, and with wise management it should be possible to make a working adjustment between the interests of the naturalist, the farmer, and the holiday-maker. These are areas that are agriculturally of low productivity, and it might be argued that they should be surrendered to the tourist industry. This would be a mistake. Holiday-makers go to the country, but they do not go to empty country. They want both services and companionship, and the size of population necessary to maintain a high amenity value is greater than that needed to service the tourist industry. Thus the need, and the opportunity, to maintain vigorous local communities as centres to which holiday-makers can go. Farming, forestry, and tourism should be together in Britain's hill country.

To these competing needs for land must be added the need for land for urban growth and industrial expansion. And this emphasizes the basic problem with which we are faced. To provide the food, the water, and the recreational areas we need for our present urban population will take all our limited resources in land. Yet inexorably our population grows, our cities grow, and the pressure on our land increases. In all our thinking, population growth is accepted as inevitable, and indeed it is, in the sense that any action to control it will only be effective after a substantial lapse of time. We are now familiar with the 'population explosion', and with the predictions of hunger or intolerable overcrowding in times beyond the limit of the lives of most of us. But very few of us have accepted the population problem as one which we should face and solve. We may reasonably hope that our resources in land will be sufficient, if wisely managed, to meet the needs of our expanding population for our lifetime. But, even on the most optimistic forecast, that leaves us barely time to meet what we can foresee of the needs of the twenty-first century. We find the population problems of our own race difficult for the same reason. We have the knowledge and the technology for control, but we lack the vision to plan and initiate a programme that we know will take several human generations to bring to fruition.

This is a matter of our hopes and ambitions for our own children. The problems of young people in an urban environment, and the stress and disorientation they suffer, are apparent already. No doubt there is still much we can do to mitigate the strains of urban life, and to maximize its advantages. But do we really believe that a population twice the present size—as it may well be a century hence—can live and work and enjoy adequate leisure and recreation within the confines of this island? And if we do not, now is the time to set about ensuring that our numbers are stabilized.

We need first a target figure. I would like to set 40 millions, though I believe that, short of catastrophe, it would take two centuries to achieve it. Perhaps more important than a target figure, we need a social philosophy that will embrace the concepts and consequences of a stable population. This will come easily to a biologist, who is accustomed to thinking of growth in terms of a sigmoid curve, with a slow start, a grand period, and a levelling off to an asymptote. The ecological concept of the climax involves a stable population, within which individuals grow and mature and die, while the community maintains its vigour and stability.

The heart of the whole matter is, of course, the birth rate. The fall in the birth rate to less than replacement rate in the 1930s and during the 1939–45 war shows how sensitive our community is to constraints on our multiplication such as economic depression and the hazards of war. We may be encouraged to believe, therefore, that if we really appreciated the threat to our children's well-being posed by unrestricted increase in their numbers, we might take advantage of the techniques of control that are available to us. Surely we can learn to take account of the fact that large families are detrimental to the interests of our children later in their lives, and to accept as normal a family size of one or two, or occasionally three, children. For, make no mistake, Britain already carries a population as great as the environment can support without degeneration, and it will call for all the knowledge and skill we can command to prevent irreparable damage before we achieve a stable population even if we set about stabilization without delay.

This is the great remaining challenge of our time. We have mastered the physical world and the world of biology. We ourselves remain untamed. Our greatest need is to master the threat of our own numbers.

THE BRITISH ASSOCIATION IN NOTTINGHAM — A CENTURY AGO

EXACTLY a century ago the British Association for the Advancement of Science met, for the thirty-fifth time, at Nottingham. Its influence in Britain was then at its height. Close on 2,000 people were members, and the membership was sufficiently permanent for its names to be printed at the end of each annual report. Most of the sections which now exist then also held their separate meetings, although the sections individually and the general assembly of the British Association as a whole made a practice of passing resolutions on matters that seemed to them to be of public importance. The Nottingham meeting was serious and concerned with a number of administrative matters such as the association's spending on scientific research. It was also, however, a cheerful meeting. As always the new president delivered his address at 8 o'clock, there was a soirée the following evening, and evening discourses on the Friday and Monday—the second of them by Joseph Hooker on insular flora. After another soirée on the Tuesday the meeting broke up with a discussion on the afternoon of Wednesday, August 29, at which the proceedings of the general committee were reported to the general meeting as a whole, and the whole body of the membership was given an account of how the committee had decided to spend its resources. At that time the association was reasonably prosperous. From a few years after its formation it had begun making small grants of money to those engaged on scientific research. In most years something of the order of £1,000 was spent on these activities and, after the thin time which the association apparently experienced in the late 1840s, the funds available were sufficient for it to allocate £1,750 13*s.* 4*d.* to scientific research at its meeting in Nottingham in 1866. The present treasurer will no doubt envy the state of affairs which allowed the association to lay out these funds from its income derived almost exclusively from subscriptions —dividends were then a mere £250 a year.

The variety of the general committee's interests is quite apparent from the report of its proceedings. In the first place, it was concerned with the affairs of the Kew Observatory and indeed spent £600 on supporting the work there. During the year the Observatory calibrated a dip circle for a Russian naval officer and did similar work for the Indian Survey. The Observatory was also engaged in the instrumentation of the survey being carried out of Zanzibar, and calibrated instruments for the Admiralty as well. Self-recording magnetographs were in fashion and Kew played a leading part in instructing workers from what is now called the Commonwealth, as well as from Russia and the United States, in the operation of these devices. Mr. Whipple, described as the Magnetical Assistant, is commended for his diligence. The Observatory was also deeply engaged in gravity surveys in India, and a Mr. Loewy at the Observatory was charged with special responsibility for seeing whether "Captain Kater's pendulum is still in a state to justify its adoption as an instrument to give correct determination of the lengths of the second's pendulum".

Sunspots were recorded. The Government was given advice about the setting up of a meteorological department, and Kew volunteered to be the first station. The Observatory asked the council of the British Association to consider favourably a request that a young clerk should be employed to tabulate magnetic and meteorological recordings at the Observatory.

The British Association was also preoccupied with what was called its Lunar Committee—a body of men among whom Sir John Herschel and Mr. J. N. Lockyer (who later founded this journal) were prominent. In 1866 they were given £120 to spend, and one of the products of their work is to be found in a report of the meeting at Nottingham as an attempt to construct a map of the Moon 100 in. in diameter. In retrospect the report of the committee's work is striking for the detail and care with which it tackled the problem of estimating the shapes and sizes of objects visible on the surface of the Moon. There is also a detailed discussion of the problem of deciding on reference points for lunar mapping and, in the drafts of the map which were available at Nottingham, attempts were made to indicate that some parts of the Moon were "higher" or "lower" than others. In its description of the crater Hipparchus, the committee was able to say: "The north boundary differs in a very marked degree from the S.W., inasmuch as the land on the S.W. rises to a considerable elevation, while on the N.N.E. it is depressed. The north boundary consists of cliffs which do not appear to rise much, if at all, above the surface of Hipparchus. It is this feature which occasions the evanescent character of Hipparchus, so that in about forty-eight hours after the terminator has passed it, this boundary is no longer discernible." The committee's careful listing of craters and other features on the Moon's surface was compiled from drawings and photographs by professional and amateur observatories throughout the country and abroad. The committee had no illusions about the difficulties of this work, and emphasized at several points in its report at Nottingham that "the map is not intended to be a perfect or complete lunar map, but only a guide to observers in obtaining data from the complete map".

The Committee on Electrical Standards was reappointed in 1866 and was to do valuable work throughout much of the nineteenth century. The Nottingham meeting was also told of the work done by a committee on "Uniformity of Weights and Measures" which boasted in its report that "during the year steps of great importance have been taken to promote the adoption of one common decimal system of weights and measures both at home and abroad". A conference had been held in Frankfurt on this subject. The committee complained that this conference had adopted a curious proposal that the metric system should be linked to the English system by defining a foot as three decimetres, but it was heartened by the way in which the United States Congress had in the previous year introduced bills making the use of the metric system lawful in the United States. The committee promised to press the cause of decimalization at the then impending exhibition in Paris in 1867, recording with

satisfaction that interest in decimalization in India was high but that administrators in India were divided about the virtues of different systems. At home the picture was less cheerful. "The only legislative measure recently passed is one for transferring to the Board of Trade the Department of Weights and Measures previously connected with the Office of the Comptroller of the Exchequer". The committee complained that there was no provision for the acquisition of standard metric weights and measures. "The law on the subject is in a very anomalous state." It recorded that a deputation had called on the President of the Board of Trade and that the noises of goodwill which he made were of no value because "the session was too far advanced and nothing has been done". The committee wanted to see education "among the young" on the metric system, a change of heart among the pharmacists, the adoption of the metric system by the railways, and a continuing effort by itself to promote the cause of decimalization.

As it happens, the cause of astronomical observations in the southern hemisphere was as much an issue in 1866 as it is a century later. The observation of meteors was also being encouraged by the British Association, and the committee responsible for this reported at Nottingham details of several visible meteors going back to an observation in 1768 on Cook's voyage around the world, but mostly collected by devoted amateurs and members of the British Association in the previous decade.

Perhaps the most adventurous of the British Association's projects was the work of the Balloon Committee, including "Colonel Sykes, Mr. Airy, Lord Wrottesley, Sir David Brewster, Sir J. Herschel, Bart., Dr. Robinson, Dr. Fairbairn, Dr. Tyndall, Dr. W. A. Miller, and Mr. Glaischer". During the year the committee had sponsored three flights by balloon with the object of collecting physical and meteorological information. One ascent took place from Woolwich Arsenal in October 1965. Mr. James Glaisher took off after the Sun had gone down, chiefly because the committee was anxious to have information about the temperature lapse in the lower atmosphere at night. Mr. Glaisher was surprised to find that the temperature did not lapse at all but actually increased with height up to 1,900 ft. He was also surprised to find that the humidity decreased with height. Mr. Glaisher made an attempt to measure ozone with slips of paper containing chemical reagents. He had trouble with his Davy lamp, which was the only way of reading his instruments. He was overcome with the brilliance of the sight of London from the balloon and felt it "impossible to convey any adequate idea of the brilliant effect of London viewed from an elevation of 1,300 ft. on a clear night when the air is free of mist". In the event the balloon crossed London by the Marble Arch and the Harrow Road and came down at Highmoor in Oxfordshire after dawn. One of Mr. Glaisher's conclusions was that it would be valuable to carry telescopes on balloons to high altitudes so that an observation might be made of the Milky Way and other stars.

Two other ascents that year seemed to be less successful. In December 1865 the temperature lapse was marked, but the balloon was buffeted much by the winds, and a lamp was put out by accident at 2,400 ft. (by which time the temperature was down to freezing) so that the journey was abandoned. Not until April 1866 was another ascent possible, and this time the journey started from Windsor and finished in Sussex. The committee of the association agreed to continue with the balloon flights and allocated a further £50 to the work of the committee—a modest amount, it would appear, in all the circumstances.

The less spectacular parts of the association's work also have a curiously up-to-date appearance. There was, for example, a committee concerned with the transmission of sound under water, whose formation had been prompted by experiments carried out in 1826 in the Lake of Geneva, and whose motive was to find some way of communicating between two ships "in company at sea, or between a ship and the coast during foggy weather". Another committee was exploring Palestine; the archaeology of Kent's Hole in Devon was supported with £100; and there were projects to excavate fossil elephants from Malta, fossil crustacea from wherever they could be found, fauna from the Kilkenny coalfields, and similar palaeontological work in Iceland, Ireland and Scotland. Finally, the association was exercised by the problem of the performance of steam ships and the need to make ships' plates impenetrable to bullets and other projectiles. Much of the work was carried out at Shoeburyness where shots were fired at ships armoured with various kinds of plating. One of the conclusions was a suggestion as to how wooden ships might be most effectively armoured with steel and iron. The committee was able to make suggestions about the tactics to be followed by ships so as to minimize the danger that their armour would prove ineffectual. It also commented on the relative advantages of the American and English systems of artillery; the Americans were apparently inclined to use heavy shot at low velocity in the hope of shattering the armour, while the British Navy looked for penetration of the armour with the intention of killing the crew, damaging the machinery and sinking the vessel. By 1866 the committee was not in a position to take a firm line about the advantages or disadvantages of the two systems.

Compared with contemporary meetings of the British Association, the attention paid a century ago to matters like these may seem remarkable. In practice the general committee of the British Association did even more to sponsor research by drawing attention to problems which needed solution, and, in this spirit, it encouraged an investigation of methods of solving simultaneous equations, the study of the chemistry of cast iron, and the difficult matter of how best (if at all) to present scientific evidence in courts of law.

As was the custom in the nineteenth century, the address by the president, Mr. William Robert Grove, Q.C., M.A., F.R.S., was an attempt to survey the then state of science in Britain. He began his address, however, with a declaration about the importance of public understanding of science. "It is sad to see the number of so-called educated men who, travelling by railway, voyaging by steamboat, consulting the almanac for the time of sunrise or full-moon, have not the most elementary knowledge of a steam-engine, a barometer, or a quadrant; and who will listen with a half-confessed faith to the most idle predictions as to weather or cometic influences, while they are in a state of crass ignorance as to the cause of the trade-winds or the form of a comet's path. May we hope that the slight infiltration of scientific studies, now happily commenced, will extend till it occupies its fair space in the education of the young, and that those who may be able learnedly to discourse on the Eolic digamma will not be ashamed of knowing the principles on which the action of an air-pump, an electrical machine, or a telescope depends, and will not, as Bacon complained of his contemporaries, despise such knowledge as something mean and mechanical."

In the second half of the nineteenth century the members of the British Association were also concerned to understand what astronomy was doing. The orbits of the double stars were easy enough to understand, but how could nebulae be accounted for in terms of gravitation as known on the surface of the Earth? Meteorites were also a puzzle, especially because they seemed to radiate from particular points in the sky. It was remarkable to the then president that the number of asteroids had increased so that there were a total of eighty-eight planets, and the notion that the space between Mars and Jupiter might be filled with planets varying in size from Jupiter to a cannon ball was already current.

But why should the Earth be so dense? On the assumption that meteorites are a kind of primeval rock, and the

suggestion—due to a French geologist—that rocks become more like meteorites the further their source beneath the surface of the Earth, it was still a puzzle to know why the average specific gravity of the Earth should be between five and six and why that of olivine was a mere 3·3. The explanation suggested by the president was that the oxidation of rocks was confined to regions near the surface of the Earth and that the deeper rocks were more dense because they were free from oxygen.

Mr. Grove was also interested by the measurement of the spectrum of a star which appeared suddenly on May 12, 1866, "equal in brilliancy to a star of the second magnitude". Its brightness diminished in a few days and its spectrum was sufficiently unusual, with bright emission lines superimposed on a continuous spectrum, to suggest that something new was happening. As to the surface of the Moon, the appearance of the craters "is not unlike that seen on the surface of some metals such as bismuth, when cooling from fusion and just previous to solidifying". May it not therefore be that the Moon is really substantially metallic with an oxide coating too thin to be seen? This at least was the suggestion, and one of the reasons why the British Association was anxious to keep its lunar committee at work, but the president admitted that the problem "needs more examination and study before any positive opinion can be pronounced". No doubt the frustration of not knowing what the Moon was made of helped the president to complain, as he did with some bitterness, that instruments ought to be improved.

With Joule a member, and actively engaged on much of the association's work, it is not surprising that the presidential address should have taken up the equivalence of heat and mechanical energy. The president himself had been impressed with an experiment demonstrating this in an unfamiliar way. "A train of multiplying wheels ended with a small metallic wheel which, when the train was put in motion, revolved with extreme rapidity against the periphery of the next wheel, a wooden one. In the metallic wheel was placed a small piece of phosphorus, and as long as the wheels revolved, the phosphorus remained unchanged, but the moment the last wheel was stopped by moving a small lever attached to it, the phosphorus burst into flame. My object was to show that while motion of the mass continued, heat was not generated, but that when this was arrested, the force continuing to operate, the motion of the mass became heat in the particles. The experiment differed from that of Rumford's cannon-boring and Davy's friction of ice in showing that there was no heat while the motion was unresisted, but that the heat was in some way dependent on the motion being impeded or arrested. We have now become so accustomed to this view that whenever we find motion resisted we look to heat, electricity, or some other force as the necessary and inevitable result." But where does heat energy come from? The president suggested that there must be a sharp distinction between influences such as heat and influences such as magnetism, which must be "cosmical and not merely terrestrial". There is no connexion to be found between sunspots and magnetism. And as to the heat of the Sun itself, the theory that this might be caused by the impact of meteorites was not convincing because it was hard to believe there could be enough meteorites.

The president was also perplexed by what is known as Albers's Paradox, pointing out that it was hard to imagine what could be happening to the radiation from the Sun and smaller stars. "If the universe have no limit and it is difficult to conceive one, heat and light should be everywhere uniform; and yet more is given off than is received by each cosmical body, for otherwise night would be as light and as warm as day. What becomes of the enormous force thus apparently non-recurrent in the same form? Does it return as palpable motion? Does it move or contribute to move suns and planets? and can it be conceived as a force similar to that which Newton speculated on as universally repulsive and capable of being substituted for universal attraction? We are in no position at present to answer such questions as these; but I know of no problem in celestial dynamics more deeply interesting than this, and we may be no further removed from its solution than the predecessors of Newton were from the simple dynamical relation of matter to matter which that potent intellect detected and demonstrated."

Thanks to his understanding of molecular physics, the president was able to be entirely confident that the heat delivered up by burning coal really comes from the Sun much earlier, at the time of its formation. He pointed out, however, that coal fields would become exhausted and that it was impossible to predict what changes would then be necessary if energy were to be used for practical purposes. "The waste of fuel in ordinary operations is enormous, and can be much economized by already known processes. It is true that we are, at present, far from seeing a practical mode of replacing that granary of force the coal-fields; but we may with confidence rely on invention being in this case, as in others, born of necessity, when the necessity arises.

"I will not further pursue this subject; at a time when science and civilization cannot prevent large tracts of country being irrigated by human blood in order to gratify the ambition of a few restless men, it seems an over-refined sensibility to occupy ourselves with providing means for our descendants in the tenth generation to warm their dwellings or propel their locomotives."

But there was electricity just round the corner. The president pointed out that "Mr. Wilde and Mr. Holz" had found that it was possible to increase "electrical power" by coupling electrical coils and electro-magnets together. "There seems hardly a limit to the extent to which mechanical may be converted into electrical force." There were also experiments with machines which "Mr. Holz" had been experimenting with.

The tone of the president's address in 1866 was optimistic. "As phlogiston and similar creations of the mind have passed away, so with hypothetic fluids, imponderable matters, specific ethers, and other inventions of entities made to vary according to the requirements of the theorist, I believe the day is approaching when these will be dispensed with, and when the two fundamental conceptions of matter and motion will be found sufficient to explain physical phenomena." He was, of course, before his time.

The aftermath of the great argument about evolution, which took place at Oxford in 1862, was still perplexing the association. The president in 1866 set out to summarize the arguments for and against. His task was made easier by the controversy then raging in France between Pasteur and Pouchet on spontaneous generation, although Mr. Grove gave victory to Pasteur. He was particularly impressed with Pasteur's argument that the assertion of spontaneous generation had become possible only for more and more "lower forms of life" as experimental techniques had become better. But there were difficulties about talking about the origin of species without a definition of what a species really consists of. "The more gaps between species are filled up by the discovery of intermediate varieties, the stronger becomes the argument for transmutation and the weaker that for successive creations." Indeed, the president then was a firm believer in continuity. He confessed that he leant to the view that the successive changes in organic beings do not take place by sudden leaps and said that "if the facts are stronger in favour of one theory than another it would be an affectation of impartiality to make the balance appear equipoised". The prejudices of education were against new views, he said. The acid test was whether a new theory would "remove more difficulties, require fewer assumptions and present more consistency of observed facts than that which it seeks to supersede".

NOTTINGHAM BETWEEN THE WARS

The third annual meeting to be held in Nottingham convened on September 1, 1937. The programme and the proceedings were similar in form to those of the nineteenth century, yet the problems of the twentieth century, practical as well as intellectual, were also plainly evident.

THE meeting of the British Association at Nottingham in 1937 was the third to have been held there, and was by all accounts successful and stimulating. The association was at that time deeply engaged in a number of issues of public importance, ranging from the importance of adult education in science to the planning of land use in Britain. The proceedings were enlivened by the appearance of H. G. Wells as president of the Educational Section, and by his eloquent plea for a sensitive appreciation of the character of education and its role in the modern world (see page 1061, this supplement). This was also the year in which George VI agreed to become patron of the British Association, and in which the then president, Sir Edward Poulton, undertook to represent the British Association at the Coronation on May 12. The balance sheet was in a reasonably healthy condition, and if there were warning signs of the difficulties which at present cause the treasurer such anguish, there was no cause to be unduly worried by them.

The Nottingham meeting was inaugurated at the Albert Hall, Derby Road, on September 1, 1937. The president spoke on the *History of Evolutionary Thought, as recorded at Meetings of the British Association*, and concerned himself with a review of the doctrine of evolution from its foundation through the mid-nineteenth century to the development of cytogenetics in this century. The meetings of the sections were held at what was then known as the University College of Nottingham. There were evening discourses on the Friday and Monday, the first by Dr. R. E. Slade on *Grass and the National Food Supply* and by Professor (later Sir) James Gray on the *Mentality of Fishes*.

Financially, the mid-thirties were a watershed for the British Association, for it was then that the association began to find it difficult to finance its scientific activities out of the income from membership subscriptions and investment revenue. The total budget for the year worked out at something less than £5,000, while investments produced a cheerful £1,500 and membership subscriptions somewhat more than £2,000 even in a year that was only moderately well attended. What with the sale of publications and occasional large donations, the association could cover its modest outgoings comfortably, and yet spare some hundreds of pounds each year for the support of scientific research. In addition there was a substantial expenditure on small grants for research from various special funds administered by the council of the British Association, so that the total expenditure on research projects in 1937 amounted to £720.

Even so, Mr. P. G. H. Boswell, the general treasurer, was worried. He pointed out that the association had not found it possible to meet its target of an annual allocation of £500 to a contingency fund, and that the accumulated surplus over five years was merely £1,940. He was also concerned that the association's support of research projects of various kinds had increasingly tended to become support for long-established committees. Like all charitable foundations, the association wished to regard itself as an initiator of new work. "The true function of the association, in making grants to research committees, is the initiation of particular pieces of research rather than their quasi-permanent endowment." But wishes are one thing and realities another; alternative sponsors for work begun were apparently as hard to come by in the thirties as they are now.

In the thirties, the various sections of the association were still passing resolutions on various matters of scientific or public importance. Frequently the council of the association, which alone was empowered to act on the basis of sectional resolutions, was also required to decide what should be done about them, and the report of the meeting in 1937 includes records that the council had found it impossible to act on a resolution passed the previous year at Blackpool, by the Chemistry Section, and which declared that the "extent to which chemistry is applied for beneficient purposes in connection with the industry of the British nation and the health of its citizens is enormously greater than the scope of its employment for purposes of warfare". As a result, the resolution went on, "chemists as a body view with grave concern the increasing use of science for destructive ends".

At Nottingham itself, the sections of the association were earnestly productive of resolutions. The mathematicians and physicists, for example, were sad to note, "on the occasion of a visit to the grave of George Green, the world-famous mathematician of Nottingham", that "deterioration is taking place in the tombstone, and would respectfully suggest that representations should be made to the proper authorities to take such steps as seem fit to maintain in good condition the resting place of this renowned man". Green, who worked for a time as a miller but later graduated from Cambridge as a mathematician, was, of course, the man who did much to put into mathematical language the work of Faraday and others on electro-magnetism.

The zoologists at Nottingham were anxious that Lord Rothschild's house at Tring should continue to be used as a centre for research and as a museum, even though it had passed into the hands of the British Museum. The geographers made a gentle protest at the decision by the published. The engineers wanted the council of the British Association to use its influence with the engineering institutions so as to create better channels for the exchange and dissemination of information about engineering research and development. The anthropologists wanted anthropology made compulsory in the studies of probationer civil servants in India and Burma. Zoologists and others asked for some public investigation of the ways in which wild animals—pests and others—were dealt with in British agriculture; one of the questions at issue was whether the gin trap was humane or otherwise.

In the late thirties the research committees were more numerous than the sections of the association. One of them—the committee on seismological investigations—remains alive, and in 1966 includes at least one member who was active in the late thirties. But the Mathematics and Physics Section was also engaged on the calculation of mathematical tables, and, in collaboration with the chemists, on the determination of thermal conductivities of rocks by making direct measurements in deep mines

and boreholes. Through the activities of the seismological committee, the British Association had become the sponsor of much detailed work, and, by its support, the University Observatory at Oxford was able to contribute to the work of the Seismological Survey. The six Milne–Shaw seismographs belonging to the association were scattered around the world at Oxford, Edinburgh, and in Australia and South Africa. It was largely because of the association's support for seismology that the Oxford Observatory was able to equip itself with a large brass globe some 18 in. in diameter and conveniently ruled and drilled with holes so as to assist in fixing the epicentres of earthquakes.

The Committee on Mathematical Tables was busy on Bessel Functions, and about to start work on the tabulation of Airey Integrals. During the year the committee made arrangements for its mechanical computing machine to be housed at the Galton Laboratory at University College, London, under the eye of Professor R. A. Fisher, and plans were in hand to employ a full-time operator (out of a budget of £200). At the same time, the Committee on the Measurement of Thermal Conductivities in Rocks completed plans for drilling a borehole 100 ft. deep, at a cost of £40, having convinced itself that thermal conductivity could be inferred without much inaccuracy from the measurements of temperature which could be made at various depths.

The geologists were particularly active. The committee responsible for collecting photographs of particular geological interest was able to add 154 items to its collection of nearly 9,000 photographs. A project was under way to ensure that full advantage should be taken of quarry working in the oolite at Stow-on-the-Wold to collect what evidence there might be of fossil reptiles, and a great many specimens came to light during the year. The quarries on which this interest was lavished had previously yielded up some splendid dinosaur remains.

The excavations at Kent's Cavern near Torquay, in which a committee of the association was first engaged a century ago, were still in progress. During the year a pit was dug in the floor of the cavern, and from it was excavated a substantial quantity of mammalian remains but only a few flints to indicate human presence. In Derbyshire, the cave known as the Whalley Rock Shelter had been found to be a primitive workshop site, with a yield of some hundreds of pieces of stone artefacts. Yet another committee was hard at work on the excavation of ancient mining sites in Wales and Northern Ireland, and was able to date with some accuracy the succession of improved techniques at a refuse dump on the Great Orme (Llandudno), and in particular to demonstrate that the Romans had worked there.

The principal work of the research committees, at least so far as the meeting at Nottingham was concerned, was in education. The geologists had been particularly concerned to make a study of the ways in which the teaching of geology in the schools could be improved, and this will no doubt be considered a curious premonition of the discussions to be held at Nottingham this year on the teaching of geology. In 1937, as now, the geologists felt neglected by the school curriculum, but at Nottingham they were more interested in showing how geology could be introduced into the school curriculum than with making the general case that geology should not be neglected. They were apparently encouraged by the way in which the school examinations in the thirties were being reorganized in such a way as to make a more general study of science a commonplace in grammar schools, and they argued that geology was a particularly suitable subject for study in those schools sited near what were called "natural geological laboratories". The committee also considered that the industrial demand for geologists would grow rapidly (though it did not cite exploration for petroleum as one of the causes of growing demand) with the result that there would be a dearth of suitably trained people "unless something is done to stimulate the entry of students into geological courses".

The committee argued that it was particularly important to include some teaching of geology early in the school career of most schoolchildren because "only a small proportion of those who enter for the various school examinations pass on to university work. Most of them take up posts in industry and commerce at once. Of these, a considerable proportion who have no further academic training obtain posts where they are sooner or later concerned with mining, building, engineering or other problems in which even a small acquaintance with geological matters would be of real assistance. In ordinary life, too, opportunities for using scientific knowledge are continually increasing in number. The applications of geology are certainly not fewer or less important than those of other sciences. Unless some work is introduced into school curricula, not only will there be a serious restriction in the numbers who will seek to take up geology as a profession, but many who may be later concerned with the applications of geology will hardly know of the existence of a science which has close contacts with their work".

The other educational theme to dominate the proceedings at Nottingham in 1937 was that of adult education in science. This had been a continuing concern of the association since the early thirties. By 1937 the committee responsible for the work had been able to collect a mass of information about the extent of adult education in Britain. As a result, it felt confident enough to present to the meeting at Nottingham a detailed report showing in great detail the place of science in adult education as it was and as it should be.

This cause was close to the association's heart. The Committee on *Science in Adult Education* produced for the Nottingham meeting a detailed analysis of the then current practice, which showed that only some seven or eight per cent of the various adult education courses—run by evening institutes, the Workers' Educational Association and by extra-mural departments of universities—were devoted to scientific subjects. Scientific studies were most neglected in the south-east of England and London, where they took up only one or two per cent of the time of the evening institutes. In the hope of making the spread of education in science for adults easier, the committee drew up detailed syllabuses for studies in astronomy, anthropology, biology and the like. This activity chimed in well with the presidential address to the section on Education Science in Nottingham that year.

For the rest, the programme for 1937 has a curiously familiar appearance. There was a symposium on the industrial use of X-rays led by Sir William Bragg, a paper on rate processes by Henry Eyring, and talk about the best way of observing eclipses and of introducing algebra into the school mathematics curriculum. The chemists were told about chemotherapy and—by W. T. Astbury—about the X-ray analysis of protein structures. Between them the geologists made a thorough survey of the Midlands, and the zoologists ranged from sex ratios in wild animals to the technique of recording bird song. There was some economics of an academic character, a paper on the possible use of electrical vibrations in television, a paper on *Palaeolithic Man in Nottinghamshire* and an anthropological study of the painted headboards on horse-drawn carts. The physiologists, much moved by what Wells had said about the need for a liberal education in science, made a concerted plea for the inclusion of physiology in the education of all young people.

By all ordinary tests, the meeting was a success. Altogether there were 2,027 people in attendance at various times, roughly half of them for the duration of the meeting. There were four or five hundred casual visitors and persons described in the reports as "foreigners".

H. G. WELLS ON EDUCATION*

In 1937 Mr. H. G. Wells was the president of the Section of the British Association on Educational Science. The substance of his address to the session, delivered on Thursday September 2, 1937, is reproduced here because it faithfully if brilliantly reflects the flavour of the British Association in the thirties, because of the historical importance of Wells's ideas on education, and also as a way of recalling that this year is the centenary of Wells's birth.

SECTION L of the British Association is of necessity one of the least specialized of all sections. Its interests spread far beyond professional limitations. It is a section where anyone who is, so to speak, a *citizen at large* may hope to play a part that is not altogether an impertinent intrusion. And it is in the character of a citizen at large that I have accepted the very great honour that you have offered me in making me the president of this section. I have no other claim whatever on your attention. Since the remote days when as a needy adventurer I taught as non-resident master in a private school, invigilated at London University examinations, raided the diploma examinations of the College of Preceptors for the money prizes offered, and, in the most commercial spirit, crammed candidates for the science examinations of the university, I have spent very few hours indeed in educational institutions. Most of those were spent in the capacity of an enquiring and keenly interested parent at Oundle School. I doubt if there is any member of this section who has not had five times as much teaching experience as I have, and who is not competent to instruct me on all questions of method and educational organization and machinery. So I will run no risks by embarking on questions of that sort. But, on the other hand, if I know very little of educational methods and machinery I have had a certain amount of special experience in what those methods produce and what that machine turns out. I have been keenly interested for a number of years, and particularly since the war, in public thought and public reactions, in what people know and think and what they are ready to believe. What they know and think and what they are ready to believe impresses me as remarkably poor stuff. A general ignorance—even in respectable quarters—of some of the most elementary realities of the political and social life of the world is, I believe, mainly accountable for much of the discomfort and menace of our times. The uninstructed public intelligence of our community is feeble and convulsive. It is still a herd intelligence. It tyrannizes here and yields to tyranny there. What is called elementary education throughout the world does not in fact educate, because it does not properly inform. I realized this very acutely during the latter stages of the war and it has been plain in my mind ever since. It led to my taking an active part in the production of various outlines and summaries of contemporary knowledge. Necessarily they had the defects and limitations of a private adventure, but in making them I learnt a great deal about—what shall I say ?—the contents of the minds our schools are turning out as taught.

And so now I am proposing to concentrate the attention of this Section for this meeting on the question of what is *taught as fact*, that is to say on the *informative side of educational work*. For this year I suggest we give the questions of drill, skills, art, music, the teaching of languages, mathematics and other symbols, physical training and development, a rest, and that we concentrate on the inquiry: *What are we telling young people directly about the world in which they are to live* ?

*Reproduced by permission of Professor G. P. Wells.

Now when I set myself to review the field of inquiry I have thus defined, I found it was necessary to take a number of very practical preliminary issues into account. As educators we are going to ask what is the subject-matter of a general education ? What do we want known ? And how do we want it known ? What is the essential framework of knowledge that should be established in the normal citizen of our modern community ? What is the irreducible minimum of knowledge for a responsible human being to-day ?

I say irreducible minimum—and I do so, because I know at least enough of school work to know the grim significance of the school time-table and of the leaving school age. Under contemporary conditions our only prospect of securing a mental accord throughout the community is by laying a common foundation of knowledge and ideas in the school years. No one believes to-day, as our grandparents—perhaps for most of you it would be better to say great-grandparents—believed, that education had an end somewhere about adolescence. Young people then left school or college under the imputation that no one could teach them any more. There has been a quiet but complete revolution in people's ideas in this respect and now it is recognized almost universally that people in a modern community must be learners to the end of their days.

Nevertheless it is true that what I may call the main beams and girders of the mental framework must be laid down, soundly or unsoundly, before the close of adolescence. We live under conditions where it seems we are still only able to afford for the majority of our young people, freedom from economic exploitation, teachers even of the cheapest sort and some educational equipment, up to the age of 14 or 15, and we have to fit our projects to that. And even if we were free to carry on with unlimited time and unrestrained teaching resources, it would still be in those opening years that the framework of the mind would have to be made. We have got to see therefore that whatever we propose as this irreducible minimum of knowledge must be imparted between infancy and, at most, the fifteenth or sixteenth year.

And next let us turn to another relentlessly inelastic packing-case and that is the school time-table. How many hours in the week have we got for this job in hand ? The maximum school hours we have available are something round about thirty, but out of this we have to take time for what I may call the non-informative teaching, the native and foreign language teaching, teaching to read, teaching to write clearly, basic mathematical work, drawing, various forms of manual training, music and so forth. A certain amount of information may be mixed in with these subjects but not very much. They are not what I mean by informative subjects. By the time we are through with these non-informative subjects, I doubt if at the most generous estimate we can apportion more than six hours a week to essentially informative work. Then let us, still erring on the side of generosity, assume that there are 40 weeks of schooling in the year. That gives us a maximum of 240 hours in the year. And if we take ten

years of schooling as an average human being's preparation for life and if we disregard the ravages made on our school time by measles, chicken-pox, whooping-cough, coronations and occasions of public rejoicing, we are given 2,400 hours as all that we can hope for as our time allowance for building up a coherent picture of the world, the essential foundation of knowledge and ideas, in the minds of our people.

Our question becomes therefore: 'What should people know—whatever else they don't know? Whatever else we may leave over—for leisure-time reading, for being picked up or studied afterwards—what is the irreducible minimum that we ought to teach as clearly, strongly and conclusively as we know how?'

We begin telling true stories of the past and of other lands. We open out the child's mind to a realization that the sort of life it is living is not the only life that has been lived and that human life in the past has been different from what it is to-day and on the whole that it has been progressive. We shall have to teach a little about law and robbers, kings and conquests, but I see no need at this stage to afflict the growing mind with dates and dynastic particulars. I hope the time is not far distant when children even of eight or nine will be freed from the persuasion that history is a magic recital beginning 'William the Conqueror, 1066'. Concurrently, we ought to make the weather and the mud pie our introduction to what Huxley christened long ago as Elementary Physiography. We ought to build up simple and clear ideas from natural experience.

We start a study of the states of matter with the boiling, evaporation, freezing and so on of water and go on to elementary physics and chemistry. Local topography can form the basis of geography. We shall have to let our learner into the secret that the world is a globe—and for a time I think that has to be a bit of dogmatic teaching. It is not so easy as many people suppose to prove that the world is spherical and that proof may very well be left to make an exercise in logic later on in the education. Then comes biology. Education, I rejoice to see, is rapidly becoming more natural, more biological. Most young children are ready to learn a great deal more than most teachers can give them about animals. I think we might easily turn the bear, the wolf, the tiger and the ape from holy terrors and nightmare material into sympathetic creatures, if we brought some realization of how these creatures live, what their real excitements are, how they are sometimes timid, into the teaching. I don't think that descriptive botany is very suitable for young children. Flowers and leaves and berries are bright and attractive, a factor in aesthetic education, but I doubt if, in itself, vegetation can hold the attention of the young. But directly we begin to deal with plants as hiding-places, homes and food for birds and beasts, the little boy or girl lights up and learns. And with this natural elementary zoology and botany we should begin elementary physiology. How plants and animals live, and what health means for them.

There I think you have stuff enough for all the three or four hundred hours we can afford for the foundation stage of knowledge. Outside this substantial teaching of school hours the child will be reading and indulging in imaginative play—and making that clear distinction children do learn to make between truth and fantasy—about fairyland, magic carpets and seven league boots, and all the rest of it. So far as my convictions go I think that the less young children have either in or out of school of what has hitherto figured as *history*, the better. I do not see either the charm or the educational benefit of making an important subject of the criminal history of royalty, the murder of the Princes in the Tower, the wives of Henry the Eighth, the families of Edward and James I, the mistresses of Charles II, Sweet Nell of Old Drury, and all the rest of it. I suggest that the sooner we get all that unpleasant stuff out of schools, and the sooner that we forget the border bickerings of England, France, Scotland, Ireland and Wales, Bannockburn, Flodden, Crecy and Agincourt, the nearer our world will be to a sane outlook on life. In this survey of what a common citizen should know I am doing my best to elbow the scandals and revenges which once passed as English history into an obscure corner or out of the picture altogether.

But I am not proposing to eliminate history from education—far from it. You will see how large a proportion of our treasure of 2,400 hours I am proposing to give to history. This next section represents about 800 to 1,000 pre-adolescent hours. It is the school-boy–school-girl stage. And here the history is planned to bring home to the new generation the reality that the world is now one community. I believe that the crazy combative patriotism that plainly threatens to destroy civilization to-day is very largely begotten by the schoolmaster and the schoolmistress in their history lessons. They take the growing mind at a naturally barbaric phase and they inflame and fix its barbarism. I think we underrate the formative effect of this perpetual reiteration of how *we* won, how *our* Empire grew and how relatively splendid *we* have been in every department of life. We are blinded by habit and custom to the way it infects these growing minds with the chronic and nearly incurable disease of national egotism. Equally mischievous is the furtive anti-patriotism of the leftish teacher. I suggest that we take on our history from the simple descriptive anthropology of the elementary stage to the story of the early civilizations.

We are dealing here with material that was not even available for the school-masters and mistresses who taught our fathers. It did not exist. But now we have the most lovely stuff to hand, far more exciting and far more valuable than the quarrels of Henry II and a Becket or the peculiar unpleasantness of King James or King John. Archaeologists have been piecing together a record of the growth of the primary of civilizations and the developing roles of priest, king, farmer, warrior, the succession of stone and copper and iron, the appearance of horse and road and shipping in the expansions of those primordial communities. It is a far finer story to tell a boy or girl and there is no reason why it should not be told. Swinging down on these early civilizations came first the Semitic-speaking peoples and then the Aryan-speakers. Persian, Macedonian, Roman followed one another, Christendom inherited from Rome and Islam from Persia, and the world began to assume the shapes we know to-day.

Look at our time-table and what we have to teach. If we give history four-tenths of all the time we have for imparting knowledge, that still gives us at most something a little short of 400 hours altogether. Even if we think it desirable to perplex another generation with the myths of the Creation, the Flood, the Chosen People and so forth, we haven't got the time for it—any more than we have the time for the really quite unedifying records of all the Kings and Queens of England and their claims on this and that. No reason why much of that stuff should not be picked up in private reading—by those who like that sort of thing. But so far as the school time-table goes we are faced with a plain alternative. One thing or the other. Great history or hole-and-corner history? The story of mankind or the narrow, self-righteous, blinkered stories of the British and the Jews?

There is a lot more we have to put into the heads of our young people over and above history. It is the main subject of instruction but, even so, it is not even half of the informative work that ought to be got through in this school stage. We have to consider the collateral subject of geography and a general survey of the world. We may have a little mapmaking here, but I take it what is needed most are reasonably precise ideas of the various types of country and the distinctive floras and faunas of the main regions of the world. We do not want our budding citizens

to chant lists of capes and rivers, but we do want them to have a real picture in their minds of the Amazon forests, the pampas, the various phases in the course of the Nile, the landscape of Labrador and so on, and also we want something like a realization of the sort of human life that is led in these regions. We have enormous resources now in cheap photography, in films and so forth, that even our fathers never dreamt of—to make all this vivid and real. New methods are needed to handle these new instruments, but they need not be overwhelmingly costly.

Geography and history run into each other in this respect and, on the other hand, geography reaches over to biology. Here again our schools lag some fifty years behind contemporary knowledge. The past half-century has written a fascinating history of the succession of living things in time and made plain all sorts of processes in the prosperity, decline, extinction and replacement of species. We can sketch the wonderful and inspiring story of life now from its beginning.

And finally, we have the science of inanimate matter. In a world of machinery, optical instruments, electricity, radio and so forth we want to lay a sound foundation of pure physics and chemistry on the most modern lines—for everyone. Some of this work will no doubt overlap the mathematical teaching. And finally, to meet awakening curiosity and take the morbidity out of it, we have to tell our young people, and especially our young townspeople, about the working of their bodies, about reproduction and about the chief diseases, enfeeblements and accidents that lie in wait for them in the world.

That, I think, completes my summary of all the information we can hope to give in the lower school stage. And as I make it I am acutely aware of your unspoken comment. *With such teachers as we have* ! Well, I think that it is a better rule of life, *first* to make sure of what you want and then set about getting it, rather than to consider what you can easily, safely and meanly get, and then set about reconciling yourself to it. I admit we cannot have a modern education without a modernized type of teacher. Everything I am saying now implies a demand for more and better teachers—with better equipment. And these teachers will have to be kept *fresh*. It is stipulated in most leases that we should paint our houses outside every three years and inside every seven years, but nobody ever thinks of doing up a school teacher. There are teachers at work in this country who haven't been painted inside for fifty years. They must be damp and rotten. Two-thirds of the teaching profession now is in urgent need of being either reconditioned or superannuated. In this advancing world the reconditioning of both the medical and the scholastic practitioner is becoming a very urgent problem indeed, but it is not one that I can deal with here.

And there is another matter also closely allied to this question of the rejuvenation of teachers, at which I can only glance now, and that is the bringing of school books up to date. In this informative section of school work there is hardly a subject in which knowledge is not being vigorously revised and added to. Our school work does not follow up contemporary digesting. Still less do our school libraries. They are ten, fifteen years out of date with much of their information.

Then our new citizens have to understand something of the broad elements in our modern social structure. They should be given an account of the present phase of communication and trade, of production and invention, and above all they need whatever plain knowledge is available about the conventions of property and money. On these conventions human property stands, and the efficiency of their working is entirely dependent on the general state of mind throughout the world. We know now that what used to be called the inexorable laws of political economy and the laws of monetary science are really no more than rash generalizations about human behaviour, supported by a maximum of pompous verbiage and a minimum of scientific observation. Most of our young people come on to adult life, to employment, business and the rest of it, blankly ignorant even of the way in which money has changed slavery and serfdom into wages and employment and how its fluctuations in value make the industrial windmills spin or flag. They are not even warned of the significance of such words as inflation or deflation, and the wage earners are the helpless prey at every turn towards prosperity of the savings-snatching financier. Any plausible monetary charlatan can secure their ignorant votes. They know no better. They cannot help themselves. Yet the subject of property and money—together they make one subject because money is only the fluid form of property—is scarcely touched on in any stage in the education of any class in our community. They know nothing about it; they are as innocent as young lambs and born like them for shearing.

Thus I budget, so to speak, for our 2,400 hours of informative teaching. We have brought our young people to the upper form, the upper standard. Most of them are now going into employment or special training and so taking on a role in the collective life. But there remain some very essential things which cannot be brought into school teaching, not through any want of time, but because of the immaturity of the growing mind. If we are to build a real modern civilization we must go on with definite informative instruction into and even beyond adolescence. Children and young people are likely to be less numerous proportionally in the years ahead of us in all the more civilized populations, and we cannot afford to consume them in premature employment after the fashion of the preceding centuries.

Social organization is equally a matter for definite information. 'We are all socialists nowadays.' Everybody has been repeating that after the late Lord Rosebery for years and years.

A certain elementary training in statistical method is becoming as necessary for anyone living in this world of to-day as reading and writing. I am asking for this much contemporary history as the crowning phase, the graduation phase of our knowledge-giving. After that much foundation, the informative side of education may well be left to look after itself.

I put [this] before you as a statement of my convictions. I do not know how it will impress you and I will not anticipate your criticisms. It may seem impossibly bold and Utopian. But we are living in a world in which a battleship costs £8 million, in which we can raise an extra £400 million for armaments with only a slight Stock Exchange qualm, and which has seen the Zeppelin, the radio, the bombing aeroplane come absolutely out of nothing since 1900. And our schools are drooling along much as they were drooling along 37 years ago.

There is only one thing I would say in conclusion. Please do me the justice to remember that this is a project for Knowledge Organization only and solely. It is not an entire scheme of education. It is only a part and a limited part of education—the factual side of education. There are 168 hours in the week and I am dealing with the use of rather less than six during the school year of less than 40 weeks—for 10 years. It is no good saying, as though it were an objection to my paper or to me, that I neglect or repudiate spiritual, emotional and aesthetic values. They are not disregarded, but they have no place at all in this particular educational scheme. I have said nothing about music, dancing, drawing exercise and so on and so forth. Not because I would exclude them from education but because they do not fall into the limits of my subject. You no more want these lovely and elementary things mixed up with a conspectus of knowledge than you want playfulness in an ordnance map or whimsicality on a clock face. But the spiritual, emotional, aesthetic lives our children are likely to lead will hardly be worth living, unless they are sustained by such a clear, full and sufficient knowledge as I have ventured to put before you here.

CRISIS AND CHALLENGE

The annual report for 1965–66 talks of financial crisis and intellectual challenge. Where will the money come from to support the new activities which have been started? How will the annual meeting be changed so as to make a greater impact on the membership and the rest of the country?

THE dominant part of the annual report of the British Association for 1965–66, which will by now have been presented to the General Committee at Nottingham, is the report of the General Treasurer, Mr. I. H. Cox. According to what he says, the British Association faces a "grave crisis" in its affairs. In the year past it has been drawing on its reserves, and is likely to have to do so again in the year ahead. Though income is not actually falling, the costs of the projects on which the association has set its heart are rising steadily, with the result that the hunt for economies, which has perplexed the association for the past decade, must continue.

The financial position is all too simple. The British Association no longer has a comfortable cushion of investments on which to fall back. Ironically, the market value of the securities which it owns is hardly different (at £41,000) from what it was thirty years ago. The income from investments is less than 3·5 per cent of the total budget (in 1965–66) of £66,000. Moreover, membership subscriptions are no longer sufficient to cover a substantial part of the cost of keeping going, even though the subscription has recently been raised to four guineas (£4·2) and even though the generosity of local industries and institutions is usually sufficient to cover the cost of the annual meeting. (At Nottingham, the overhead costs will be borne by the ratepayers of that city.) The result is that the association has now to support itself increasingly by means of grants and donations from foundations, industries and public bodies. Making sure that grants continue is necessarily a continuing cause for anxiety. Trying to arrange that they should be increased must often seem a superhuman undertaking.

The immediate outlook is this. Income in the year to the end of March 1966 was £60,000, or roughly £5,000 less than in the previous year. Although the membership increased, and the association sold more copies of its publication *The Advancement of Science*, the past year was also one in which a number of covenants made seven years ago by industrial companies came to an end. (Even so, the association still received £22,000, or a third of its total income, from this source.) But as income has fallen, opportunities to spend money have increased. The result is that the General Treasurer expects that the association will be in deficit in the current year as well, even though it will begin to enjoy a grant from the Ministry of Technology intended to allow the association to embark on a programme for persuading young people to take an interest in technology. It is no wonder that the officials of the association feel curiously frustrated by circumstances outside their own control. This is how the treasurer puts it:

"As to the future, I regret my inability to be more reassuring than my predecessor in his last report. For any inter-meeting activities to take place (and this is an area in which the association's work has developed fast) advance financial provision must be made, and the council has felt that it could not but approve a budget for 1966–67 which again anticipates a deficit—£5,000—even after substantial economies in staff and a further drastic reduction in subventions to branches and area committees which permits no material development. As a continuing policy, however, budgeting for deficit is clearly suicidal and, as I write, the closest reassessment of the association's deployment of its slender funds is being made and new sources of income are being energetically sought. In the course of this I greatly hope that new financial policies may emerge in time for me to report upon them to the General Committee when it meets in Nottingham in August.

"Let there be no doubt, however, that for the present the association faces a grave crisis in its affairs. This is all the more ironic and regrettable in view of the recent reorientation of its activities more specifically to meet the needs of the times by creating a better understanding of the commercial and intellectual life of the nation, and by offering a forum where different disciplines can be brought to bear on matters of national moment, and broadening the horizon of young people so that those with the aptitude for careers in science and technology may discover themselves, and be discovered, before it is too late. Of the pressing need for these things, none can have serious doubt; that they lie squarely within the role and competence of the British Association is also generally accepted; what appears to be wrongly assumed, however, is that we can somehow continue to perform our national function without adequate support from public funds. Business, industry and charitable foundations are already exhibiting their faith. The further sum we sought—and still seek—from this other source to afford a stable central structure from which all else stems (£12,500 a year and pound for pound up to another £25,000) seems a pitifully small sum to ask and be refused."

The last passage is a reference to the way in which the association has been trying to persuade the Department of Education and Science—so far without success—to increase the annual payment of £12,500 towards the general cost of the association's work. Elsewhere in his report the Treasurer says that it is "deeply disappointing" to have to report that this request had been declined in November 1965. It is, no doubt, a measure of the association's despair about the financial outlook that it can risk being as openly critical about a government department on which it will have to continue to rely for a measure of financial support, at least in the foreseeable future.

There is, of course, no doubt that the character of the association has changed enormously in recent years. The form of the annual meeting may have remained more or less unchanged in the past century, but its flavour is now very different from what it used to be. The association's direct support of research and innovation has died away to a trickle—though the Seismological Committee continues, and although the geologists are working on the improvement of the curriculum and the anthropologists are studying burial sites and ancient field systems.

There has, however, been a rapid growth of the association's work in schools and with the public. The annual report makes no bones about the importance which is now attached to these activities.

"For the last decade the association has done wonders, within the limits imposed by its scant financial resources, in providing throughout the year and all over the country a massive and successful service of lectures and meetings for schools and other audiences, at which the pattern of

the annual meeting is translated into a less formal and often most exciting style."

The annual report goes on to draw attention to its work with visual aids and in various other studies intended to help with education and educational experiment.

The lecture service is now the central component of the association's contemporary claim on public attention—and financial support. How does it work? The headquarters of the British Association, the two branches (the Southern Branch centred on Southampton and the West Midlands Branch at Birmingham) and the nineteen area committees which now exist all undertake to provide speakers on scientific subjects for audiences in schools and those provided by adult organizations. During 1965–66 a total of 1,719 lectures was provided, four-fifths of them by the area organizations. In the annual report now current, the association claims that the total audience during the year was 128,000, including nearly 40,000 adults. This is marginally less than the corresponding figure for 1964–65.

The total cost of providing the lectures seems to have been about £24,000, of which some £7,000 came from local sources—chiefly local education authorities approached by area committees of the British Association. This works out at 3*s*. 9*d*. for each member of the audience, although the net cost to the association was only three-quarters of this. The annual report says that during 1964–65 the area committees were asked to restrict their spending on lectures and other similar activities, and that a still further reduction has been called for in the current financial year. The extent to which this will hamper activities will no doubt be determined by the success with which individual area committees are able to raise extra funds from their local authorities.

The association also has encouraging news to report about its work with young people. For some years it has been organizing "Science Fairs" at which young people from schools exhibit the results of project work carried out either at school or in their spare time. The area committees of the British Association take the initiative in organizing these events, though some of the work and all of the money are provided by the *Sunday Times*. (Dr. T. A. Margerison of the *Sunday Times* has played a particularly valuable part in the development of this work.) In the past few months the science fairs have been turned into a remarkably successful series of television programmes, thus setting at rest the anxieties on the part of the council of the British Association as these are expressed in the annual report. Another new venture is the organization of what is called a young scientists' association based on Southampton, and there is also a scheme for replicating a meeting for young people at which visits to factories and other industrial establishments play a prominent part.

The association also conducts a number of programmes supported by ear-marked grants, chiefly from charitable foundations, which run to something like £5,000 a year. One of these is a project to maintain a continuing interest in the development of school curricula in mathematics. Another is intended to make it easier for teacher training colleges to keep in touch with scientific developments, usually by receiving a distinguished lecturer on some special topic, but sometimes by making visits to scientific or industrial establishments. Then there is a scheme for encouraging youth clubs to carry out scientific investigations, frequently in the form of ecological investigations spread over a considerable interval of time. The association also maintains a visual aids committee, with a full-time executive officer who arranges programmes for the annual meeting of the association and who keeps liaison with film makers and film users, in industry and education, in the hope of increasing the mutual benefit of the interested parties.

Though the annual meeting may now seem less important than it used to, the association quite properly says, in the current annual report, that this meeting is a "focal point" for the rest of its work. If the meeting is now less of a means of communication between professional scientists than it was a century ago, it retains the pattern the original purpose of which was to provide an annual review of developments in the whole of science in the course of the preceding year. Joint discussions involving members and speakers from different sections have always been a feature of the British Association, and just as there is now a committee intended to find ways of exploring common ground between botanists and zoologists in cytology and genetics, so in the past there have been similar committees attempting, with varying degrees of success, to raise for discussion topics lying across the conventional boundaries between different branches of science.

In the past year or so the officers and officials of the association have been looking for ways of giving this annual occasion more bite, and more impact on public affairs. In this spirit, there has appeared on the annual programme an increasing number of public discussions, involving members of different sections of the association, on issues of some topical importance. In recent years there have been symposia on topics such as the provision of food for the impoverished half of the world and the supply of fuel and other sources of power. This year, at Nottingham, there are to be discussions of three topical issues—supersonic aircraft, drugs and their safety, and the problem of meeting the steadily increasing demand for fresh water from countries of all kinds, advanced and otherwise. As things have turned out, the public discussions of these questions have tended to become rehearsals of well known points of view. This was particularly true of the symposium at Cambridge in 1965 at which the distinguished heads of the nationalized industries concerned with the production of fuel outlined the well known policies of their organizations. The trouble, of course, is that an open meeting of the British Association is not an ideal setting for critics of official fuel policy to have their say. It would seem only fair to recall that in 1937 there was a discussion as vigorous as any likely to take place this year at Nottingham on the issue of how best to use the land of Britain. The British Association as such had earlier taken sides on this question by sending a resolution to the Government asking that a statutory body should be established to undertake what was called town and country planning, but there were several of the members who did not take kindly to the word *planning*.

None of these considerations is directly relevant to the anxieties which beset the Treasurer. There may even be some comfort for him in knowing that the day is gone when the ability of the association to spend money is determined by the size of the attendance at the annual meeting; that, too, could be embarrassing, at least in years when bad weather or competing attractions kept people away from the annual meeting. In any case, there is no longer a city in the United Kingdom that could accommodate so many people at the same time that their membership fees would keep the association going from one year to the next. Yet the meeting remains the focal point, and its success will inevitably determine how easily the association as a whole can win the attention of those who must in future keep it supplied with funds.

There is every reason to believe that the council of the association is aware of the problems which confront it. The annual report, which is remarkably frank for documents of this kind, says that "Institutions no less than individuals must, if they are to survive, react quickly and effectively to changes in the world around them. It is therefore satisfying to report that the council has, during the year, engaged in continuing discussions aimed at redefining both the association's purposes in the modern world and at clarifying the ways in which it can most effectively implement those purposes".

LEEDS, 1967

Sir Willis Jackson

SIR WILLIS JACKSON, who will be President of the British Association in 1966–67, and who will deliver the Presidential Address at Leeds in 1967, has been an elder statesman for as long as most people can remember, but he is a mere 62 years old. He was born in Burnley and educated there and at the University of Manchester. His first job was as a lecturer in electrical engineering in the then College of Technology at Manchester, from where he moved to Oxford in the early thirties. He went into industry, with Metropolitan Vickers Electrical Co., for a brief spell before the Second World War and then became professor of what was called electrotechnics at the University of Manchester and professor of electrical engineering at the Imperial College of Science and Technology. His public reputation was enormously enhanced by his spell as Director of Research and Education at Associated Electrical Industries (Manchester), Ltd., in the fifties. There Sir Willis was responsible for building up an efficient and imaginative scheme for the training of people at all levels, especially young apprentices. The success of the training scheme was such that it became a model followed widely by other similarly placed companies in British industry. Sir Willis left industry to become head of the Department of Electrical Engineering at Imperial College in 1961.

For the past decade Sir Willis has also been extremely active as a member of committees concerned with public policy towards science and technology. He joined the Advisory Council on Scientific Policy in 1961 and has remained the chairman of the sub-committee responsible for scientific manpower since he took over from Sir Solly Zuckerman in 1963. The sub-committee has recently been preparing an up-to-date survey of the use made of scientific manpower in Britain which is due to be published in September 1966. The chances are that this document will have an important bearing on the discussions now going on about the spending of public money on science on one hand and technology on the other.

The election of Sir Willis Jackson as President for 1967 will do much to gratify the wish of the British Association to be more intimately concerned with technology.

DUNDEE, 1968

Dame Kathleen Lonsdale

SCIENTISTS throughout the United Kingdom, whether suffragettes or not, will be delighted to learn that Professor Dame Kathleen Lonsdale has been elected President of the British Association for the Advancement of Science for 1968. Professor Lonsdale was one of the first two women to be elected to the Royal Society of London; she now becomes the first woman to hold the presidency of the British Association—an election long overdue.

A pioneer in the field of X-ray crystallography, Professor Lonsdale worked with Sir William Bragg's original team in the early 1920s. Since then her work has encroached on the structure of the benzene ring, magnetic anisotropy of crystals and molecules, X-ray scattering in diamonds and ice, and diamond/graphite transitions; more recently it has been applied to medical fields in which she is investigating bladder stones and other calculi.

Throughout her views on various aspects of life, science and politics there runs a strong ethical thread. Professor Lonsdale is known as a Quaker and a pacifist. She is forthright in her views, and her refusal to register for wartime duties led to a prison sentence in 1943.

She is known to hold strong views as to the moral obligations of the scientists. As citizens she believes they ought to be vigilant to see that the applications of science which ease their own conditions of life do not lead to unnecessary danger for other people. She has also said that they have a duty towards the general public and towards the statesmen and politicians to make sure that they are well informed—here perhaps lies the reason for her constant support of the activities of the British Association over many years.

Professor Lonsdale is an inspiration to all who work with her in the Department of Chemistry at University College, London, or come into contact with her through her extensive committee work with the International Union of Crystallography, the Royal Institution, and various prison and borstal institutions.

Married to Dr. T. J. Lonsdale, a scientist now retired but previously at the Road Research Laboratory, Professor Lonsdale has two daughters, one son, six grandsons and two granddaughters.

Continued from page 1050

72 and 74 Å, respectively, for the diameter of the equivalent sphere.

The result for casein illustrates one difficulty of the proposed present method for estimating molecular dimensions associated with molecules far removed from spherical shape. The κ-casein molecule has been reported to be a rod 150 Å long and 16 Å in diameter[15]. Such a molecule can be calculated to have a radius of gyration of 43 Å and an equivalent sphere radius of 19 Å. The present result by TMV precipitation indicates that the domain occupied by casein molecules is larger than either of these dimensions.

The molecular weight of dextran fractions had little effect on the threshold concentration, which indicates that a given weight of dextran occupies a volume fraction that is independent of the size of the molecules. This coincides with the observation by Laurent[6] that the effect of various dextrans on the solubility of albumin was the same for equal weights of all dextrans, regardless of the molecular weight of the dextran used. The close agreement with the data of Ogston and Woods[13], already referred to, is valuable support for the validity of the hypothesis underlying the technique.

The result obtained here for gelatine solutions also applies to gelatine gels. Unlike that with agar, the turbidity of gelatine–TMV mixtures is not affected by the sol-gel transformation, which suggests that gelatine molecules occupy the same volume in sols and gels. This is similar to the situation with dextran, where no essential difference was found in the exclusion phenomenon in gels or solutions[18].

The molecular radius found here for hyaluronic acid is less than half the value of the radius of gyration obtained by light scattering (Ogston, personal communication). It is possible that the present result is low because the space-excluding efficiency of a molecule probably decreases as the diameter of the excluding molecule increases, relative to a fixed size of excluded molecule[4]. Some compression of the hyaluronic acid molecules may be necessary to exclude the TMV particles from the interstices between the hyaluronic acid molecules.

The results shown in Table 1 suggest that, provided some caution is taken in interpreting the data, the TMV precipitation method can be used as a rapid and simple technique to obtain some idea of molecular dimensions. In its simplest form it is not necessary to measure the optical density of the turbidity achieved by adding TMV to the macromolecules. Such measurements were made here in order to establish the nature of the precipitation curves. All that is required is the detection of the 'end-point' or threshold concentration by visual observation of the lowest concentration of macromolecule required to give a visible turbidity. This will permit the technique to be applied to small volumes of sample.

I thank Prof. A. G. Ogston for valuable discussions on the mechanism of the phenomenon.

POSSIBLE LOCALIZATION OF THE GENES FOR THE KIDD BLOOD GROUP ON AN AUTOSOME INVOLVED IN A RECIPROCAL TRANSLOCATION

By MAJ HULTÉN*, J. LINDSTEN*, L. MING PEN-MING*¶, M. FRACCARO†, ANNA MANNINI†, L. TIEPOLO†, Dr. ELIZABETH B. ROBSON‡, A. HEIKEN§ and K–G. TILLINGER‖

This article describes a family in which several members show a chromosomal abnormality. It has been possible with the aid of meiotic studies to interpret this as a reciprocal translocation involving two autosomes. Studies of nineteen autosomal marker genes suggest the possible location of the genes determining the Kidd blood group system on one of the chromosomes involved in the translocation.

The family was selected for chromosomal study because a young couple (II 5 and 6 in Fig. 1) had produced a stillborn, heavily malformed daughter and had a history of one previous, spontaneous abortion. The chromosomes of the abnormal child were not examined. The mother was apparently normal, but the father showed a very slight abnormality in that the short arm of one chromo-

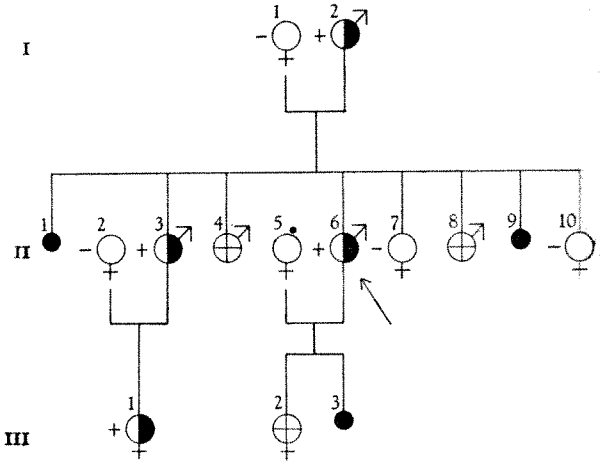

Fig. 1. Pedigree of family Z. Semifilled symbols indicate translocation carriers, empty ones chromosomally normal individuals, crossed ones individuals not studied, and small filled circles spontaneous abortions not cytogenetically analysed. The results of the Kidd blood group testing are indicated to the left of the symbols by + = Jk_a + and − = Jk_a −.

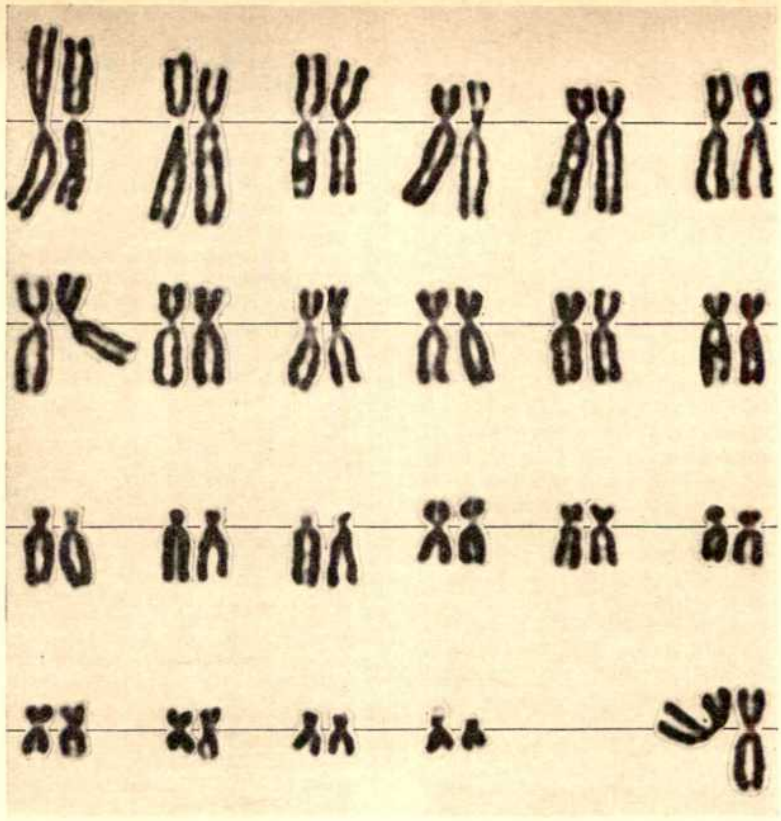

Fig. 2. Karyotype obtained from a mitotic blood cell from the niece of the propositus. Note the short, short arm on the right hand chromosome of pair No. 2.

some No. 2 was slightly shorter than usual (Fig. 2). The abnormality was very slight and in some cells it was scarcely detectable, probably because of variation in contraction of the chromosomes. A similar abnormality was detected in the grandfather, uncle and cousin, while the grandmother and two aunts showed no detectable abnormality. All these individuals, carriers of the translocation and normals, were apparently healthy.

A testicular biopsy was obtained from II 6 and it showed a normal histological picture. Altogether forty-nine cells in diakinesis or first metaphase were analysed. All cells demonstrated an apparently normal XY bivalent and one characteristic quadrivalent (Fig. 3). Twenty autosomal bivalents were found in eighteen cells, and nineteen in five cells. In the remaining twenty-six cells the exact number of bivalents could not be determined with certainty. A chain of four chromosomes was never observed, nor cells with twenty-three bivalents. Judging from the shape and size of the quadrivalent, chromosome No. 2 and one chromosome in the group 6–12 seemed to be involved in the translocation. All individuals with an abnormal karyotype could thus be considered as translocation carriers.

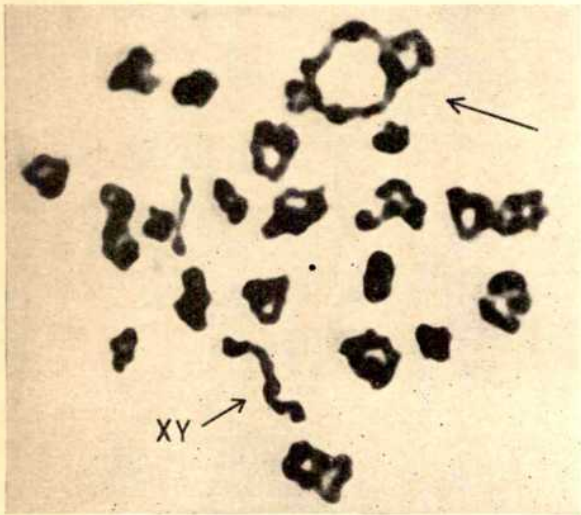

Fig. 3. First meiotic metaphase in a testicular cell from the propositus, twenty-one bivalents and one quadrivalent. The XY bivalent and the quadrivalent formed by the chromosomes involved in the translocation and their homologues are indicated by arrows.

Nineteen autosomal marker genes were investigated to determine their linkage relationships with the chromosomal abnormality. Seven systems gave information, and of these *Rh*, *MNSs*, *Hp*, *Gm* and *Gc* showed definite evidence of crossing-over with the marker chromosomes. The only one to give any suggestion of linkage was the Kidd (Jk) blood group system. The results are shown in Fig. 1. The probability of finding such a family, assuming complete linkage due to the suppression of crossing-over, is 16 : 1 in favour of linkage. Without this simplifying assumption the probability of linkage of some degree is about 7 : 1. It must be remembered, however, that the initial odds of finding linkage in these circumstances is dependent on the length of the two chromosomes involved in the translocation in relation to the total chromosomal length. If this is taken to be about 1/10, then the final odds for linkage lie between 3 : 2 in favour and 7 : 10 against. While one cannot be more precise at this stage, this family does provide a suggestion that the genes determining the Kidd red cell antigens may be located either on chromosome No. 2 or on one of the chromosomes in the group 6–12.

These investigations were supported by grants from the Swedish Cancer Society and Medical Research Council, BIOI EURATOM, the University of Pavia, and the National Heart Institute, National Institutes of Health, Bethesda, Maryland.

LETTERS TO THE EDITOR

ASTRONOMY

Neutrino Energy Losses from Vibrating Neutron Stars

IT has been suggested by Cameron[1] that the spectra of discrete X-ray sources in the sky may arise from two sources, each attributable to the presence of neutron stars: a thermal component emitted from the photosphere of the star and a non-thermal synchrotron or bremsstrahlung component emitted by electrons accelerated in a vibrating magnetosphere. It is assumed that the latter process derives its energy from stored gravitational energy in the form of radial oscillations with characteristic fundamental frequencies in the 10^3 c/s range.

Calculations by Bahcall and Wolf[2,3] indicate that neutrino cooling of non-oscillating neutron stars by way of the reactions $(n,n) \rightarrow (n,p,e \text{ or } \mu,\bar{\nu})$, $(n,\pi^-) \rightarrow (n,e \text{ or } \mu,\bar{\nu})$ and their inverses can reduce surface temperatures below observable limits in a matter of months. Tsuruta and Cameron[4] have pointed out, however, that this view is overly pessimistic because at neutron star densities ($\sim 10^{13}$–10^{16} g/cm^3) the pion-neutron interaction is predominantly repulsive which makes it unlikely that pions will be present at all. On this basis, cooling times are extended to times of the order of 10^5 years.

In this communication I shall examine Cameron's other conjecture in order to determine whether significant amounts of vibrational energy can be stored for long times. The temperature effect will be excluded by considering only zero temperature neutron stars.

If the star is in hydrostatic equilibrium the major component of its composition will be neutrons, with added traces of protons, electrons and negative muons. The abundances of these particles, in the non-interacting Fermi gas model, are easily determined by the condition imposed on their Fermi energies (including rest mass), namely,

$$E_F(n) = E_F(p) + E_F(e) = E_F(p) + E_F(\mu^-) \quad (1)$$

plus charge neutrality. In this model no pions appear until densities reach $\sim 10^{17}$ g/cm^3 (ref. 5). For this case there are no neutrino losses from neutron-neutron scatterings because only zero energy neutrinos can be emitted. If, however, the star is set into vibration so that portions of the interior are subject to sufficiently rapid density fluctuations, then equation (1) is no longer satisfied and neutrinos can be lost from the system.

Bahcall and Wolf[2,3], Finzi[6], and Ellis[7] have computed matrix elements and phase space integrals for the $(n,n) \rightarrow (n,p,e \text{ or } \mu,\bar{\nu})$ reactions in the non-zero temperature case for neutron stars in hydrostatic equilibrium. Their results are in remarkable agreement. It appears that this process will provide the dominant neutrino energy loss mechanism from vibrating neutron stars. I have followed Bahcall and Wolf's course and have used their matrix elements while adapting their phase space integral calculation to the case where equation (1) is not satisfied. We obtain, for the neutrino luminosity L_ν

$$L_\nu \approx 0{\cdot}74 \times 10^7 (\rho_N/\rho)^{\frac{1}{3}}[|\Delta_e|^8 + |\Delta_\mu|^8 p_F^2(\mu)/p_F^2(e)] \text{ ergs/g sec} \quad (2)$$

where

$$\Delta_e = E_F(n) - E_F(p) - E_F(e) \text{ MeV} \quad (3a)$$

$$\Delta_\mu = E_F(n) - E_F(p) - E_F(\mu) \text{ MeV} \quad (3b)$$

$p_F(e)$ and $p_F(\mu)$ are the electron and muon Fermi momenta, and ρ_N is nuclear density equal to $3{\cdot}7 \times 10^{14}$ g/cm^3. L_ν is a function of time because the Fermi energies and momenta change as the density changes during vibration.

A somewhat similar calculation has been performed by Finzi[8], but at only one density, so that no realistic model was used. Finzi suggested that some unknown mechanism transfers vibrational energy to the surroundings of a neutron star with a half-life of $\simeq 55$ days, thus accounting for the exponential tails of Type I supernova light curves. However, more recently Morrison and Sartori[9] have proposed a detailed theory which can account quantitatively for the shape of these light curves and the details of the observed spectra. This theory depends only on the flash of light at maximum luminosity and is thus not related to the nature of a supernova remnant.

To incorporate these results into a realistic neutron star model we have used the results of Tsuruta[5,10] based on equations of state derived from two nuclear potential calculations of Levinger and Simmons[11]. The two potentials, V_β and V_γ, yield models the density profiles of which are sufficiently different so as to represent a considerable spread in possibilities. The star is assumed to oscillate in a sinusoidal, homologous fashion such that each element of mass experiences a radial displacement proportional to its equilibrium radial distance from the stellar centre with all elements moving in phase. (Prof. A. G. W. Cameron informs me that these assumptions may be significantly in error.) The fundamental frequency is obtained from the variational principle of Misner and Zapolsky[12]. On this basis, an approximate expression for the total vibrational energy is

$$E_{\text{VIB}} \approx 2\pi\omega^2 \xi^2 \int_0^R r^4 \rho(r) dr \quad (4)$$

where ω is the circular frequency and $\xi = \delta r/r$ is the ratio of the maximum radial displacement δr of a mass element during expansion (or compression) to the equilibrium position. By the homology assumption ξ is a constant for all elements. R is the total radius.

For a given model, the rate of decrease of E_{VIB} is given by

$$\dot{E}_{\text{VIB}} = -4\pi \int_0^R L'_\nu(r) \rho(r) r^2 dr \quad (5)$$

$L'\nu(r)$ is the neutrino luminosity of equation (2) integrated over as many cycles as occur in 1 sec.

Six models have been calculated assuming an initial value of $\xi = 0{\cdot}05$. Table 1 lists the relevant parameters for each.

Table 1. NEUTRON STAR MODELS

Potential	Mass (in $M_\odot$)	Radius (in km)	E_{VIB}/ξ^2 (ergs)	ω (radians/sec)
V_β	0·34	11·7	$9{\cdot}6 \times 10^{51}$	$1{\cdot}0 \times 10^4$
V_β	0·62	7·0	$3{\cdot}3 \times 10^{52}$	$1{\cdot}96 \times 10^4$
V_β	0·89	5·7	$4{\cdot}4 \times 10^{52}$	$2{\cdot}09 \times 10^4$
V_γ	0·33	14·1	$2{\cdot}3 \times 10^{52}$	$1{\cdot}23 \times 10^4$
V_γ	1·07	12·3	$1{\cdot}7 \times 10^{53}$	$1{\cdot}67 \times 10^4$
V_γ	1·80	11·2	$1{\cdot}4 \times 10^{53}$	$1{\cdot}23 \times 10^4$

The time variation of E_{VIB} is shown in Fig. 1 for all models. It can be shown that

$$E_{\text{VIB}} \approx [E_{\text{VIB}}^{-3}(t=0) + \text{constant} \times t]^{-1/3} \quad (6)$$

where t is the elapsed time. After an elapsed time equal to the life of the Crab Nebula ($\sim 3 \times 10^{10}$ sec), vibrational

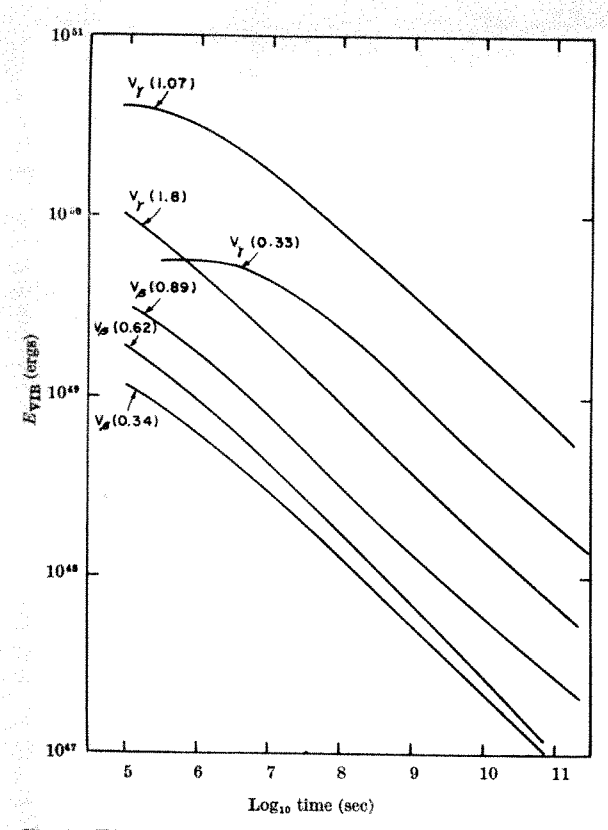

Fig. 1. Vibrational energy versus elapsed time for six neutron star models.

energies are still in the range $\gtrsim 10^{47}$ ergs for V_β models and $\gtrsim 10^{48}$ ergs for V_γ. Without knowing how efficiently vibrational energy can be dissipated into the surrounding medium, it is difficult to interpret these figures. However, the energies are probably large enough to account for the rate of electromagnetic radiation from the Crab Nebula which is $\sim 10^{37}$ ergs/sec based on figures given by Gould[13]. If this rate has been relatively constant for the last 1,000 years, then the total loss has been $\sim 3 \times 10^{47}$ ergs, which is comparable with, or less than, the vibrational energy which can still be stored at the present time. I have also calculated the decrease in vibrational energies for non-zero initial temperatures and find that the above conclusions still hold for initial temperatures as high as 10^9 °K (ref. 14).

I thank Prof. A. G. W. Cameron who suggested and guided this work, and Dr. S. Tsuruta who was prompt in making additional neutron star models and frequency calculations at my request.

Frequency Splitting of Solar Radio Bursts

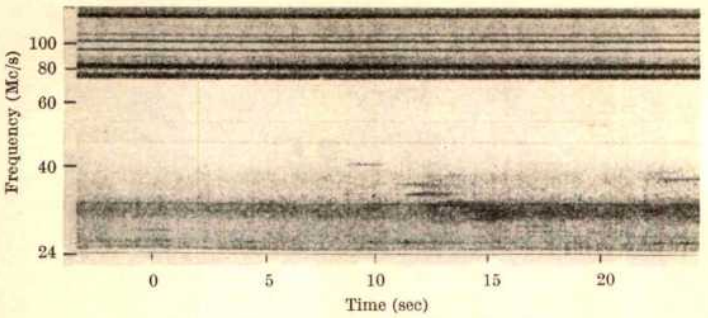
As part of a new experimental and theoretical programme of solar radio research in Tasmania, a number of dynamic spectrographs are being built to obtain information of the amplitude, polarization and direction of arrival of radio bursts with high time and frequency resolution. The first two instruments, which have been in operation since early 1965, have the following specifications: (*a*) frequency range 8–230 Mc/s, bandwidth 200 kc/s sec^{-1}, scan rate 200 sec^{-1}; (*b*) frequency range 24–28 Mc/s, bandwidth 50 kc/s sec^{-1}, scan rate 200 sec^{-1}. Each uses a fixed log periodic antenna directed obliquely into a horizontal reflecting screen. In receiver (*a*), the first oscillator frequency is swept with a varactor over the range 440–662 Mc/s and there are three intermediate frequency amplifiers at 670 Mc/s, 50 Mc/s and 10 Mc/s respectively. Records of dynamic spectra are made on 35 mm film moving at 18 in./h for 8 h each day and intermittently with a film speed of 6 in./min during solar bursts. The operation of the faster cameras is initiated by the bursts.

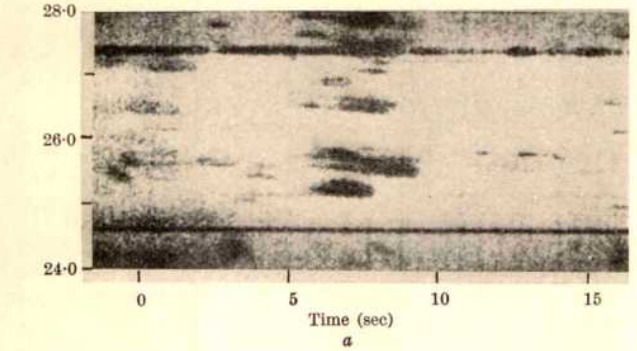
Apart from a few bursts, mainly type III, nothing of significance was recorded until the major series of radio outbursts which began on March 16, 1966, and continued until March 29. This event was characterized by a single spot group which, when observations began at 2200 U.T. on March 16, was situated at approximately 45° north latitude and 60° east of the meridian. Large numbers of type I and III bursts and drift pairs and some U-bursts were recorded.

In addition, many narrow bandwidth bursts, apparently of a type not so far reported, were observed in the frequency range 20–50 Mc/s. On the wide range records (spectrograph *a*), they appeared as sharp lines of almost constant frequency and lasting for 1–2 sec (Fig. 1). They generally occurred in groups of about ten individual bursts distributed in frequency from 20 Mc/s to 50 Mc/s, with the higher frequency components beginning slightly earlier. The frequency-time slope of the leading edges was in the range -4 Mc/s to -10 Mc/s, that is in the same range as for type III bursts. The rate of occurrence of the burst groups was approximately 10/h during March 17 and 18. With the higher frequency resolution of the 24–28 Mc/s spectrograph, the individual bursts were observed to be made up of two components separated slightly in frequency (Figs. 2*a*, *b* and *c*). The mean frequency interval was 0·12 Mc/s and its range of values 0·05–0·25 Mc/s. The centre frequency of each component normally decreased with time at the mean rate 0·1 Mc/s and the mean duration was 1·2 sec.

A possible explanation of these split pairs is the excitation of electromagnetic waves near the ordinary and extraordinary mode critical frequencies. The small frequency separation, about $fH/2$, would then imply that the source is located in a region of low magnetic field intensity ($\sim$ 0·12 oersted). The generation of two magneto-ionic modes of opposite polarizations in the solar corona has already been examined by Zeleznyakov[1] in the theory of plasma Cerenkov radiation, and it is interesting that he found the extraordinary wave will in general not be observable because of high attenuation unless the magnetic field intensity is very small. With a field intensity of 0·12 oersted, the extraordinary wave might still be seen but could be expected to be much weaker than the ordinary wave which would correspond to the lower frequency component of the split pair. However, examination of the records shows in general that the higher frequency component is the stronger. With this mechanism, the two components would have opposite polarization.

An alternative process is Doppler shifted cyclotron radiation from electrons[2,3]. It has been shown by Fung and Yip[4,5] that in the solar corona, electrons moving in the magnetic field of a sunspot may generate cyclotron radiation which will be observable mainly in the ordinary





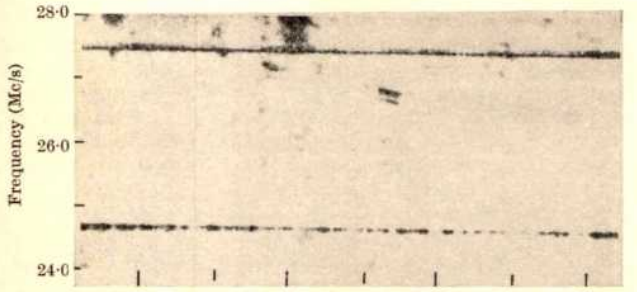


Fig. 1. Wide range record showing split pair group.

mode in the vicinity of the second harmonic of the cyclotron frequency. The frequency will depend also on the direction of emission, and two waves of differing frequencies corresponding to forward and backward emission normally will be observable. The velocity of the guiding centre would need to be only about 0·01 *c* to produce the small frequency splitting observed. If the mean direction of motion is outwards through the corona, then this velocity is consistent with the observed rate of change of the centre frequency. The polarization of both components would be ordinary in this event.

Polarization observations may thus be expected to throw more light on the origin of the split pairs, and in association with directional measurements may produce new information about the dynamics of particles and the magnetic fields in the solar corona.

This research programme is supported by the Australian Radio Research Board.

PLANETARY SCIENCE

Anti-matter Content of the Tunguska Meteor

Cowan *et al.*[1] have advanced the hypothesis that the 1908 Tunguska meteor explosion resulted from the anti-matter content of the metecrite. Although their analysis indicates a probable upper limit of 1/7 for the anti-matter content of the Tunguska meteor, this result depends to a large extent on the validity of certain assumptions used in the calculations.

The present analysis should be considered an extension of the former work and assumes as its starting point the previously determined four charged pions produced per nucleon pair annihilated. Whereas Cowan *et al.* assumed that only negatively charged pions are absorbed by atmospheric nuclei (and thus instrumental in producing carbon-14), the cross-section data of Marshak[2] indicate that the mean free path for nuclear absorption is essentially the same for both positively and negatively charged pions. This is reasonable as the pion-nucleon interaction arises mainly from the nuclear rather than electrostatic forces. If the charged pion mean free path σ for nuclear absorption is taken as 80 g cm^{-2} in air[3], it is possible to compare the fraction of pions which decay with the fraction which are absorbed provided the pion mean life is known. Horwitz *et al.*[4] report an average total energy E_T of 380 MeV per charged prong in the $p\bar{p}$ annihilation. The charged pions then have an average kinetic energy E_K of 240 MeV (the rest mass energy E_0 is 140 MeV) and a small relativistic correction to the mean life τ_m of the pion is necessary. A conservative estimate of the increased pion mean life τ' can be made by assuming an essentially constant speed equivalent to E_k = 240 MeV. Since $E_T = \gamma E_0$, $\tau'_m = \gamma\tau_m$ ($\gamma = [1-\beta^2]^{-\frac{1}{2}}$, then τ'_m = (380/140) (2·54 × 10^{-8} sec) = 6·9 × 10^{-8} sec.

If n_0 represents the total number of charged pions produced initially by annihilation reactions, then the number of pions n remaining at some later time t would be $n = n_0 \exp - \left(1/\tau'_m + \frac{\bar{\rho}\bar{v}}{\sigma}\right)t$, where v and ρ represent respectively the average pion speed and atmospheric density along the flight path. Since $\bar{\rho}\bar{v}/\sigma$ is effectively the probability of absorption per unit time, then by letting $\lambda_a = \bar{\rho}\bar{v}/\sigma$ and $\lambda'_m = 1/\tau'_m$, the above expression may be written $n = n_0 \exp - (\lambda_a + \lambda'_m)t$. Since in this form the expression for n is similar to that for branched radio-

active decay, branching ratios for decay and absorption may be defined as $R_d = \frac{\lambda'_m}{\lambda'_m + \lambda_a}$ and $R_a = \frac{\lambda_a}{\lambda'_m + \lambda_a}$, respectively. For an explosion at a height of 5 km, $\bar{\rho} = 7{\cdot}3 \times 10^{-4}$ g-cm^{-3}, and if $\bar{v} = 0{\cdot}9\ c$ ($v = 0{\cdot}93\ c$ for $E_k = 240$ MeV), then $R_d = 0{\cdot}983$ and $R_a = 0{\cdot}017$.

Whereas the previous analysis assumed that 50 per cent of the charged pions were absorbed thus producing a 7 per cent increase in radiocarbon activity, the calculations already given indicate only 1·7 per cent are absorbed thus yielding only a 0·24 per cent increase in radiocarbon activity. Although this value may only be correct to within a factor of two owing to over-all uncertainties in the initial assumptions, it is questionable whether a 0·24 per cent increase in radiocarbon activity would be detectable. Cowan *et al.* report an increase equivalent to about 1 per cent in some tree rings around 1909, but Suess[5] finds no change whatsoever in another sample. These results are consistent with the hypothesis that the Tunguska meteor was entirely anti-matter in content.

A closer look at the mechanisms which initiate thermonuclear and anti-matter explosions is now in order. Of the 200 MeV available as a result of uranium-235 fission about 85 per cent is converted immediately into kinetic energy of very short range fission fragments (less than 3 cm in air at sea level), thus liberating a tremendous amount of energy within a relatively small volume. The formation of a fireball from a fission-fusion explosion arises primarily from this phenomenon.

In contrast to this approximately 65 per cent[4] of the energy available in a $p\bar{p}$ annihilation goes into charged pions and the remainder into neutral pions (assuming the kinetic energy is the same as that of the charged pions). The charged pions which are absorbed ($\approx$ 2 per cent of the total) by atmospheric nuclei result in neutron and proton emission from excited nuclei. Because the neutron mean free path in air is much too large to permit much absorption close to the explosion centre, only proton interactions will contribute any significant amount of energy to the growth of the fireball. Thus, of the charged pions which are lost through the process of nuclear absorption, less than 1 per cent are effective in contributing to the thermal yield of the explosion.

In evaluating the contribution of the charged pions which decay (greater than 98 per cent of the total generated) to the thermal yield it is well to note that the decay products are muons and neutrinos ($\pi^+ \rightarrow \mu^+ + \nu$). The neutrinos, of course, contribute essentially no energy whatsoever to the thermal yield. The muon contribution depends on the average energy at which the pions decay. Using pion range-energy curves[3] a value of $-dE/dx = 2 \times 10^{-3}$ MeV/cm is deduced for rate of energy loss of 200 MeV pions in air at sea level. More than 98 per cent of the pions decay within six half-lives, and using the above datum, calculations show that the pions suffer little energy loss during this interval (less than 15 MeV on the average). By calculating the maximum and minimum muon energies (in the laboratory system) resulting from pion decay, the average muon kinetic energy is taken as about 160 MeV. Owing to the extremely large absorption mean free path in air, nearly all the muons will decay before being absorbed. Because the maximum kinetic energy of the electron from muon decay is 52·3 MeV in the muon reference frame, a certain portion of these decay electrons will possess enough energy in the laboratory system to initiate electronic showers and with lower energy decay electrons will aid in the development of a fireball.

As mentioned earlier, more than 30 per cent of the $p\bar{p}$ annihilation energy is channelled into neutral pions. Owing to the extremely short mean life ($\approx 10^{-15}$ sec) these pions disappear rapidly yielding mostly high energy quanta (99 per cent) and a smaller proportion (1 per cent) of electrons and positrons. The absorption mean free path[6] of 50–100 MeV quanta in air is about 67 g cm^{-2}, implying that most of this energy will be absorbed at large distances, thus adding relatively little to the thermal yield of the explosion. Thus, the over-all contribution to fireball growth from neutral pion decay electrons and positrons may be about the same as for those from muon decay.

Although qualitative in some respects, these calculations permit a comparison to be made of the energy distribution between an ordinary nuclear explosion and an anti-matter explosion. In an air burst[7] of a fission-fusion device roughly 50 per cent of the energy is dissipated in blast and shock effects, 35 per cent of the total yield appears as thermal radiation, 5 per cent as initial nuclear radiation, and 10 per cent as residual radioactivity. These percentages are of course dependent on altitude. The significant point for this type of explosion is that a major proportion of the particles emitted in the fission-fusion reactions dissipate their energy within a short distance, thus producing conditions favourable for the formation of a fireball.

In contrast the greater percentage of primary particles produced in an anti-matter explosion rapidly decay, and the secondary emissions will in general be absorbed over a relatively large volume. Qualitatively it might be expected that within a certain critical volume near the explosion centre the secondary and to a lesser extent the primary emissions would produce conditions favourable to the development of a fireball. Under these conditions it would not be surprising if the percentage of thermal yield from an anti-matter explosion was considerably less than that resulting from an ordinary nuclear explosion.

The observations of an eye-witness to the Tunguska meteor explosion are significant at this point. As Cowan *et al.* point out, the fireball did not last long. S. B. Semenov, an observer, just managed to lower his eyes as the explosion occurred, and when he looked again the fireball had disappeared. The account of P. O. Kosolopov in the same connexion has similar implications. This relatively short duration fireball (presumably only several seconds) is difficult to reconcile with the 33 sec fireball[7] to be expected from an ordinary 30 megaton thermonuclear explosion (the calculated equivalent yield of the Tunguska burst). It definitely appears that the relatively short duration fireball is reasonable evidence against the Tunguska explosion being thermonuclear in nature. A Monte Carlo calculation would be necessary to evaluate properly all the parameters involved, but it certainly seems possible that an anti-matter explosion of this yield would have a fireball of only a few seconds owing to the vastly different nuclear interactions inherent in the process itself. Finally, very recent studies indicate the possibility that certain shock haloes in biotite are of anti-matter origin[8].

Strontium : Calcium Ratio in Tourmalines from South-west England

GOLDSCHMIDT has pointed out[1] that during the cooling of an igneous magma the earliest formed calcium minerals would be poor in strontium relative to calcium while later calcium minerals would show a progressively higher

proportion of strontium to calcium. In his opinion this would be so because the calcium ions would be taken into the crystal lattice in preference to strontium, because they were more abundant and because they had a smaller ionic radius and would form a stronger bond. Other workers[2,3] have shown that the ratio of strontium : calcium in plagioclases does increase as calcium decreases with fractionation in certain igneous rock series.

Samples of tourmaline have been separated from some of the various rock types that make up the granitic masses of south-west England and their strontium and calcium content determined by emission spectrographic analysis[4]. When the ratio of strontium : calcium of each tourmaline sample is plotted against calcium content several features of interest emerge. In Fig. 1 tourmalines taken from granites, aplites and pegmatites and some of those from quartz-tourmaline rocks form a series in which both the ratio of strontium : calcium and the absolute amount of strontium increases as calcium decreases. If the granites, aplites and pegmatites are considered to make up a fractionation series then the variation in the ratio of strontium : calcium with fractionation shown by others to be present in plagioclases may also be said to exist in tourmalines from the granitic rocks of south-west England. In addition, on the basis of the low calcium content and the high ratio of strontium : calcium in their constituent tourmaline, certain quartz-tourmaline rocks can be considered to be the product of extreme fractionation.

A second generation of tourmaline, usually occurring as blue-green acicular crystals which sometimes form stellate aggregates and grow around corroded nuclei of an earlier generation of tourmaline, has long been recognized in the granites of south-west England[5] and may be attributed to late-stage hydrothermal activity. Perhaps the most striking feature of Fig. 1 is the way in which the samples (*H*), selected as of undoubted hydrothermal origin on the basis of their mode of occurrence, may be seen to be quite separate from all the other samples. The ratio of strontium : calcium for the hydrothermal samples is as much as ten times greater than that for other tourmaline samples containing similar amounts of calcium.

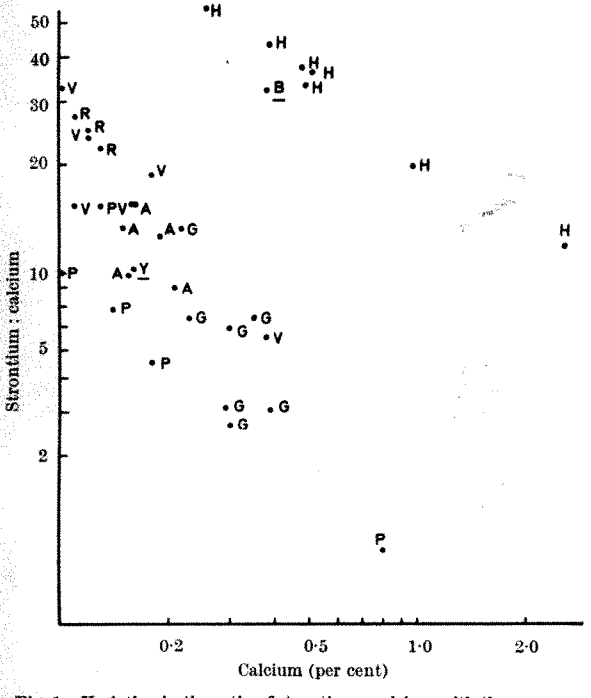

Fig. 1. Variation in the ratio of strontium : calcium with the percentage of calcium in tourmalines from south-west England. (Percentage of strontium × 1,000)/percentage of calcium is plotted against the percentage of calcium. Origin of pure tourmaline samples: *G*, granite; *A*, aplite; *P*, pegmatite; *R*, quartz-tourmaline rock; *V*, quartz-tourmaline veins; *H*, hydrothermal tourmaline; *B*, blue rim; *Y*, yellow central zone tourmaline from Castle an Dinas quarry, near Penzance.

The ratio of strontium : calcium may be used as an aid in establishing whether or not a given tourmaline sample is of hydrothermal origin. Tourmaline from a zone of reddened granite in Castle an Dinas quarry near Penzance, on examination in thin-section, was found to consist of anhedral yellow grains each with an outer zone of blue tourmaline. Samples of both the yellow and the blue tourmaline were obtained by careful hand-picking of the pure mineral fragments and analysed separately. The yellow central zone (*Y*) contains 0·16 per cent calcium and 16 p.p.m. strontium and falls into the same region in Fig. 1 as the samples from aplites. On the other hand the blue outer zone (*B*) contains 0·38 per cent calcium and 122 p.p.m. strontium and falls into the same region as the hydrothermal samples, which strongly suggests that the growth of the blue rims was of hydrothermal origin. Certain other tourmaline samples from quartz-tourmaline veins and from some quartz-tourmaline rocks were often found to have a patchy yellow and blue coloration in thin-section, and if their ratios of strontium : calcium were plotted on Fig. 1 they would fall between the fractionation series and the hydrothermal tourmalines. These samples are interpreted as having undergone some degree of hydrothermal alteration.

The ratio of strontium : calcium in tourmaline may, therefore, be used not only as an indicator of fractionation and to distinguish hydrothermal tourmaline from other varieties of tourmaline but also to detect tourmaline that has suffered some degree of subsequent hydrothermal alteration.

ENGINEERING

Wind Forces on Groups of Structures

A RECENT letter by Gunn and Malik[1] raises the possibility that the collapse of the Central Electricity Generating Board's cooling towers at Ferrybridge in 1965 might have been caused by the unusual aerodynamic loads present on this type of configuration.

Very little is known about the flow around groups of bodies, and a preliminary investigation has just been completed in this laboratory of the pressures on one cylinder in a group of cylinders as shown in Fig. 1. The cylinders, 2 in. in diameter and 28 in. high, were mounted on the floor of the 5·5 ft. by 4 ft. working section of a low speed wind tunnel and tested at a Reynolds number based on the diameter of the cylinder of 15×10^5. The pressure distribution on one of the cylinders in the rear row was measured for various angles of inclination of the group to the flow direction. The pressure tappings were placed around the cylinder in a plane 9 in. below the top.

One interesting feature of these results is that over a small angle of inclination α the force F on the cylinder in the rear row changes by almost 100 per cent. Fig. 2 shows these results, and it can be seen that if the main stream is inclined to the group at an angle of 26° then a change of $\pm$ 2° in the wind direction can produce a

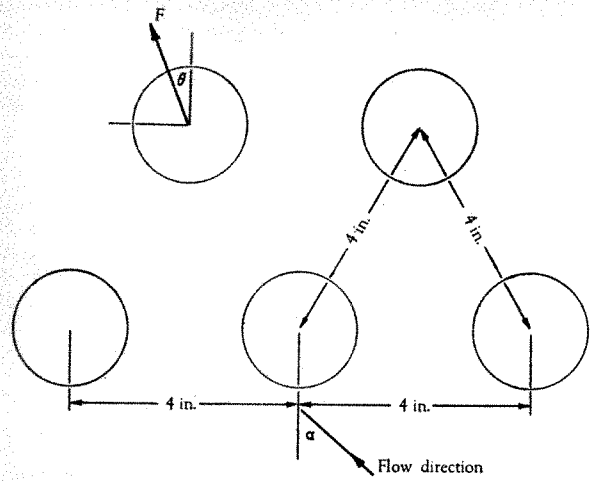

Fig. 1. Experimental configuration. Flow velocity u, density ϱ, and cylinder diameter $d = 2$ in.

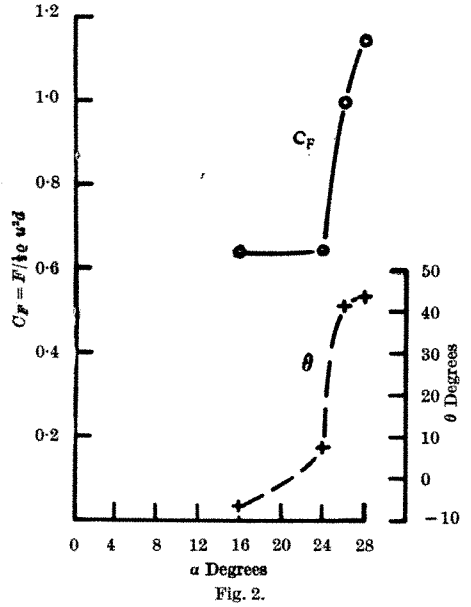

Fig. 2.

change in the non-dimensional force coefficient C_F of about 0·5. Also shown on Fig. 2 is the variation of the direction of this force with the angle α.

This result may be relevant to the collapse of the cooling towers, because it is quite conceivable that if the mean wind direction were at this critical inclination to the group and the direction of the wind were oscillating by a few degrees about this mean direction then this would produce a large fluctuating force on the towers. The frequency of the fluctuating force would be determined by the frequency of the wind oscillation and not by the frequency of oscillation of the wake of the cylinder.

The tests mentioned here were, of course, at a Reynolds number much lower than those of the actual towers, but it is thought that the flow producing these results is not very sensitive to Reynolds number.

A similar result was found earlier by Mitchell, also in this laboratory, for the flow around a group of rectangular blocks (to be published).

The Central Electricity Generating Board now considers the collapse of the cooling towers to be due to structural weakness.—Editor, *Nature*.

Flow of Gas at Low Pressure

WHEN the diameter of a round tube is very much larger than the mean free path (m.f.p.) of the molecules of a gas flowing through it the volumetric flow F of the gas in the axial z direction is given by the expression

$$F = \frac{\pi a^4}{8\mu} \frac{dp}{dz}$$

where a, μ and p are the tube radius, and the gas viscosity and pressure, respectively.

When the width to thickness ratio of a rectantular tube as well as the thickness to m.f.p. ratio are very large, the flow of gas dF per unit width dw of the tube is likewise given by the expression

$$\frac{dF}{dw} = \frac{b^3}{12\mu} \frac{dp}{dz}$$

where b designates the inner thickness of the tube.

Conversely, at low pressures when the m.f.p. is very much larger than the dimensions of a uniform tube of circumference 0 and cross-section area A extending in the z direction, and under the assumption that the accommodation coefficient is unity, that is, that molecules bounce off the walls in a Maxwellian distribution, the mass flow of gas is generally given by expressions equivalent to (1) (ref. 1)

$$Q = \frac{4}{3} \bar{c} \frac{A^2}{0} \frac{d\varrho}{dz} \qquad (1)$$

where $\bar{c}$ and ϱ designate the average speed of the molecules and the gas density respectively. It is immediately apparent that equation (1) cannot have a general application. For example, did the general cross-section consist of two parallel connected round tubes of different radii a_1 and a_2, the inequality

$$a_1^3 + a_2^3 \neq \frac{(a_1^2 + a_2^2)^2}{a_1 + a_2}$$

would demonstrate the inapplicability of (1).

When the tube is round, equation (1) can be written

$$\frac{Q}{A} = q = \frac{2}{3} \bar{c}\, a \frac{d\varrho}{dz} \qquad (2)$$

where q designates the average mass flow per unit cross-section area of the tube. This is the case in which (1) is correct, as the following calculation will verify. The method used consists of first calculating the mean free path, $\bar{e}$, of the low-pressure gas molecules in a round tube, and, second, the mean square $\overline{e_z^2}$ of the free paths projections in the axial z direction. The axial molecular diffusivity, D_z, is then given by

$$D_z = \frac{1}{2} \frac{\overline{e_z^2}}{e} \bar{c}$$

because the mean squared random travel of a molecule in the z direction in a time t is given by $2D_z t$, and the average mass flow per unit area is given by

$$q = D_z \frac{d\varrho}{dz} \qquad (3)$$

$\bar{e}$ is obtained immediately from the observation that, since the rate of molecular collisions with the tube wall is $\frac{1}{4} \bar{c}\, \nu$ per unit area, where ν designates the number of molecules per unit volume, for a single molecule in a tube of radius a, length l and wall area $2\pi a l$ we should have

$$\nu = \frac{1}{\pi a^2 l} \text{ and } \frac{\bar{c}}{\bar{e}} = \frac{1}{4} \bar{c}\, \nu \,.\, 2\pi a l = \frac{1}{2} \frac{\bar{c}}{a}$$

whence

$$\bar{e} = 2a$$

In order to calculate $\overline{e_z^2}$, a polar system of co-ordinates is placed on an element of the inner wall, the elevation δ

of any direction being measured from the axial z direction, and the azimuth φ from an inner directed normal to the tube at the point considered. $\overline{e_z^2}$ is calculated from the general formula

$$\overline{e_z^2} = \frac{\int z^2 \, d\Omega}{\int d\Omega}$$

where z designates the z projection of any path originating on the wall element and where $d\Omega$ designates any properly weighted elementary solid angle from the wall element considered. Any unweighted solid angle is given by $\sin\delta \, d\delta \, d\varphi$ and the weight $\sin\delta\cos\varphi$ must be applied to correct for the foreshortening of the elementary area for slanted directions. z is given by

$$z = \frac{2a \cos\varphi \cos\delta}{\sin\delta}$$

We obtain for $\overline{e_z^2}$

$$\overline{e_z^2} = \frac{\int_0^{\pi} d\delta \int_{-\pi/2}^{\frac{\pi}{2}} \frac{4a^2 \cos^2\varphi \cos^2\delta}{\sin^2\delta} \sin^2\delta \cos\varphi \, d\varphi}{\int_0^{\pi} d\delta \int_{-\frac{\pi}{2}}^{\frac{\pi}{2}} \sin^2\delta \cos\varphi \, d\varphi}$$

$$= \frac{4a^2 \cdot \frac{\pi}{2} \cdot \frac{4}{3}}{\frac{\pi}{2} \cdot 2} = \frac{8}{3} a^2$$

whence for D_z

$$D_z = \frac{1}{2} \frac{\frac{8}{3} a^2}{2a} \bar{c} = \frac{2}{3} a\bar{c} \qquad (4)$$

and substitution of this value for D_z in equation (3) yields equation (2).

It is illustrative to note that the average net mass flow given by equation (3) is not uniform throughout the tube. Thus, for example, we may calculate the flow through an element of unit area of the tube cross-section near the tube wall by noting that, for a uniform density gradient $d\rho/dz$, the rate of mass flow from a small area at the height z above the cross-section element considered is given by

$$\frac{\frac{1}{4}\left(\rho_0 + z \frac{d\rho}{dz}\right) \bar{c} \, d\Omega}{\int d\Omega}$$

where $d\Omega$ designates the properly weighted solid angle through which that small area is seen from the element of the tube cross-section at which the system of polar coordinates is centred, and where ρ_0 designates the gas density at that small element. The proper solid angle weight for this calculation is $\cos\delta$, which measures the foreshortening of the cross-section element for directions slanted with respect to the normal to that element, and we obtain for the z $(d\rho/dz)$ term

$$q_{lw} = \frac{\frac{1}{4}\bar{c}\frac{d\rho}{dz} \int_0^{\frac{\pi}{2}} d\delta \int_{-\frac{\pi}{2}}^{\frac{\pi}{2}} 2a \frac{\cos\varphi\cos\delta}{\sin\delta} \sin\delta\cos\delta \, d\varphi}{\int_0^{\frac{\pi}{2}} d\delta \int_{-\pi}^{\pi} \sin\delta\cos\delta \, d\varphi}$$

$$= \frac{2a}{4} \bar{c} \frac{d\rho}{dz} \frac{\frac{\pi}{4} \cdot 2}{\frac{1}{2} \cdot 2\pi} = \frac{a\bar{c}}{4} \frac{d\rho}{dz}$$

where it must be noted that the integral with respect to $d\varphi$ in the numerator extends over only half the domain of the denominator because the proximity of the wall ensures that from one half the solid angle viewed by the cross-section element the rate of molecular flow is determined by ρ_0.

q_{lw} represents, therefore, the excess of mass flow downward which results from the greater gas density above the cross-section. Likewise, the calculation of the mass flow upward would reveal a deficiency of gas flow of the same magnitude due to the lower density of the gas below the area considered, so that the total mass flow per unit area near the wall would be

$$q_w = 2q_{lw} = \frac{1}{2} a\bar{c} \frac{d\rho}{dz} \qquad (5)$$

or somewhat less than the average mass flow given by equation (4).

A similar calculation for the excess mass flow from above through an element of the cross-section in the centre of the tube would give

$$q_{lc} = \frac{1}{4} \bar{c} \frac{d\rho}{dz} \frac{\int z \, d\Omega}{\int d\Omega}$$

$$= \frac{1}{4} \bar{c} \frac{d\rho}{dz} \frac{\int_0^{\frac{\pi}{2}} d\delta \int_0^{2\pi} a \frac{\cos\delta}{\sin\delta} \sin\delta\cos\delta \, d\varphi}{\int_0^{\frac{\pi}{2}} d\delta \int_0^{2\pi} \sin\delta\cos\delta \, d\varphi}$$

$$= \frac{1}{4} a \bar{c} \frac{d\rho}{dz} \frac{\frac{\pi}{4} \cdot 2\pi}{\frac{1}{2} \cdot 2\pi} = \frac{\pi}{8} a \bar{c} \frac{d\rho}{dz}$$

and adding a like contribution resulting from the deficiency in the mass flow from below

$$q_c = 2q_{lc} = \frac{\pi}{4} a \bar{c} \frac{d\rho}{dz} \qquad (6)$$

This mass flow is greater than the average given by equation (4) which is thus seen to be intermediary between a higher flow in the tube centre and a lower flow at the tube side.

If we now consider a rectangular tube of inner width and thickness B and t, respectively, the classical formula (1) gives for the mass flow per unit area

$$q = \frac{Q}{Bt} = \frac{4}{3} \frac{\bar{c}}{Bt} \frac{B^2 t^2}{2(B+t)} \frac{d\rho}{dz} \cong \frac{2}{3} t \bar{c} \frac{d\rho}{dz} \quad , B \gg t \qquad (7)$$

When we attempt to verify equations (7) by calculating the diffusivity of molecules in the z direction, we obtain readily for $\bar{e}$, using an argument similar to the one used for the case of a round tube:

$$\bar{e} = 2t$$

On the other hand, when we calculate $\overline{e_z^2}$ we have for the elementary weighted solid angle:

$$d\Omega = \sin^2\delta \cos\varphi \, d\delta \, d\varphi$$

and for the projection z of any path:

$$z = t \frac{\cos\delta}{\cos\varphi \sin\delta}$$

and it is clear that the integral $\int z^2 d\Omega$ taken over the entire solid angle viewed from a wall element is infinite.

It can easily be verified that an infinity is also obtained when the mass flow through an element of the tube cross-section is calculated as was done for a round tube.

This result illustrates the care with which some of the subtleties of kinetic theory must be tackled and suggests that the study of gas flow at low pressure through any but round tubes may require a computer approach and a presentation of the data through multiple entry tables.

THE SOLID STATE

Rehbinder Effect in Lubricated Metal Cutting

THE mode of action by which lubricants reduce cutting forces during machining operations has been the subject of many conflicting hypotheses[1–5]. Shaw *et al.*[6] stimulated new interest in this field with the observation that carbon tetrachloride caused a reduction in cutting forces of some 10–15 per cent if applied to the workpiece surface and allowed to evaporate immediately before cutting. This phenomenon has been the subject of a recent investigation in which both $^{14}CCl_4$ and $C^{36}Cl_4$ were used to study the location and distribution of the tagged species in copper chips cut at slow speed.

The fluid was applied to the workpiece surface ahead of the advancing shear zone (Fig. 1) in sufficiently small amounts to have evaporated visibly before deformation of the surface occurred. Nevertheless, a reduction in cutting force of some 10 per cent was achieved. By taking direct activity counts on the resultant chip it was determined that chemical reaction had occurred predominantly on the rough surface of the chip remote from the chip/tool contact under these conditions. Lubrication of the chip/tool interface had not occurred. By preparing autoradiographic records from chip taper sections and also by directly counting the activity on chip surfaces progressively subjected to acid dissolution, the distribution of activity in the body of the chip was determined. There was, however, no evidence for the existence of a concentration gradient of tagged material across the chip section, which would have indicated diffusion of the applied fluid into the chip itself.

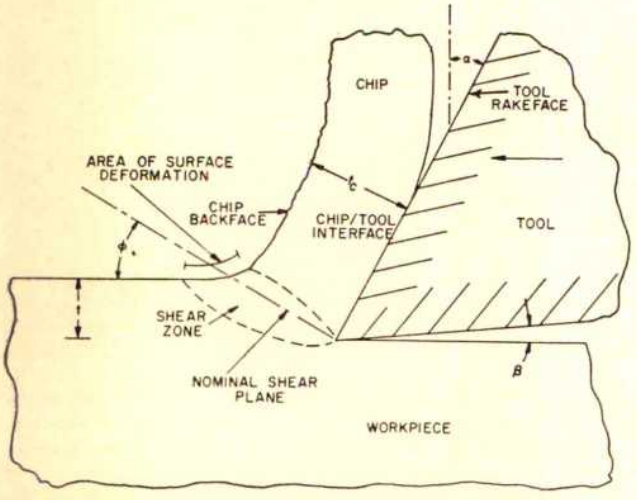

Fig. 1. Diagram showing chip formation and giving nomenclature. ϕ, Shear angle; α, rake angle; β, flank clearance angle; t, undeformed chip thickness; t_c, chip thickness.

The evidence obtained suggested that carbon tetrachloride changes the mechanical properties of the deforming metal by a purely surface chemical reaction. Some confirmation that the shear zone was sensitive to change in condition of the deforming surface area was, therefore, sought. Electropolishing the deforming area during a cut produced the same changes in cutting parameters that had previously been obtained by the reaction of carbon tetrachloride in the same area. Fig. 2 shows a dynamometer trace and longitudinal chip section for a cut—lubricated throughout with electrolyte (phosphoric acid–ethanol–water mixture)—during which the deforming surface was from time to time electropolished. The reduction of cutting force and increase in shear angle which result from what is again a purely surface effect are clearly demonstrated.

The effect of adsorbed media on the rate of strain hardening of metal single crystals was first demonstrated by Rehbinder[7], and attributed to diffusion of physically adsorbed molecules into microcracks thought to be present in the surface. It was suggested that this diffusion process caused microcracks to propagate, so weakening the metal. More recently Kramer[8] showed that, during tensile tests with single crystals of aluminium and copper which were immersed in stearic acid solutions, chemical reaction and localized solution of the test specimen accompanied a reduction in the rate of strain hardening of the metal. Removal of the surface by electropolishing the specimens during the tensile test produced similar changes in the rate of strain-hardening[9], and it was argued that the function of the surface active media used by Kramer, and earlier by Rehbinder, was to produce localized surface removal in regions of dislocation pile-up below the metal surface. Because the surface represents a

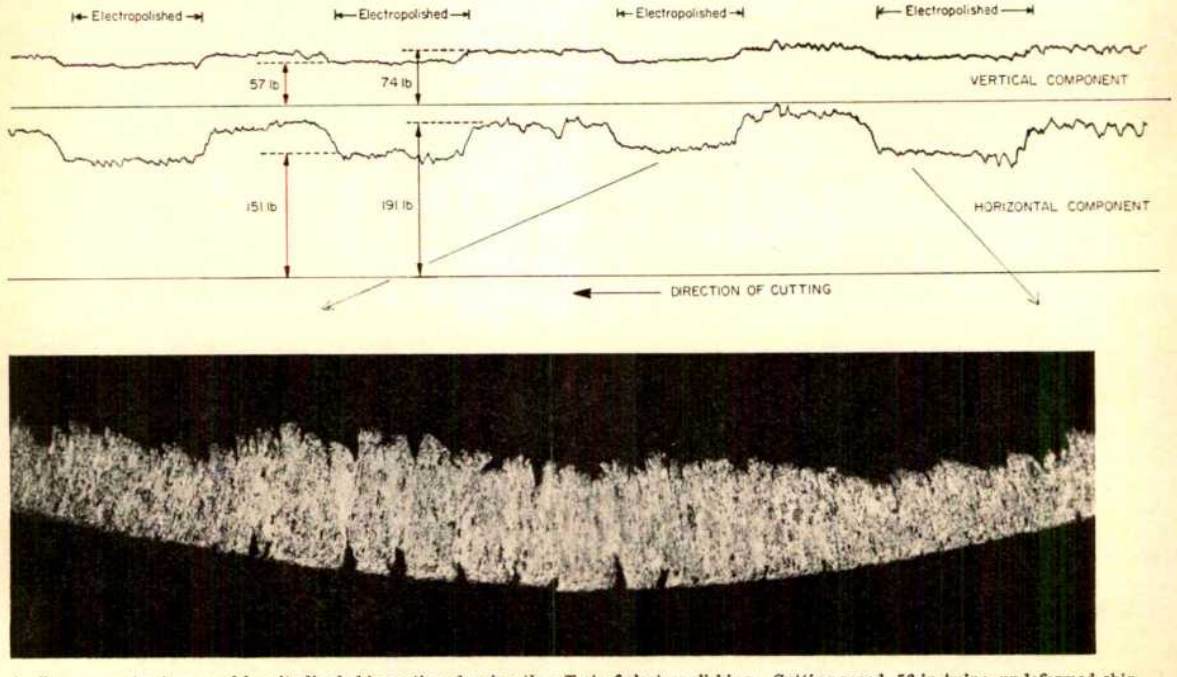

Fig. 2. Dynamometer trace and longitudinal chip section showing the effect of electropolishing. Cutting speed, 56 in./min; undeformed chip thickness, 0·004 in.; rake angle, 15°; metal, 99·3 per cent copper.

partial barrier to the egress of dislocations, removal of the surface would lower this barrier and accelerate the flow of dislocations from the crystal; in this way the rate of strain hardening of the metal undergoing deformation would be reduced.

In this investigation, because at the most only a few monolayers of carbon tetrachloride can be present on the surface at the time of deformation, solution of the reaction product is ruled out. The surface-mechanical interaction cannot be the result of localized surface removal. The emphasis has therefore been transferred from surface removal to the chemical reaction itself. It is proposed that the barrier to dislocation flow out of the metal results from the resistance to fracture of the interatomic bonds linking the atoms which constitute the surface. Passage of a dislocation out of the metal to form a slip step involves the breaking of many strong bonds and leaves the atoms forming the slip step in a high energy condition with an excess of electron charge. The presence on the crystal surface of electronegative species, which could by reaction during slip step formation take up the excess charge, must reduce the resistance of the intermetallic bonds to fracture and facilitate slip step formation. On this basis the reaction of carbon tetrachloride will accelerate dislocation flow from the metal and reduce the rate of strain hardening in the shear zone. It can be shown that a reduction of the strain hardening rate will result in the higher shear angle and reduce cutting force; these are, in fact, observed.

It appears that the surface-mechanical interaction of fluids such as carbon tetrachloride which occurs during the cutting process is basically the same phenomenon as that observed originally by Rehbinder during tensile tests with metal single crystals, and can therefore be classified as a Rehbinder effect. Further evidence has shown, however, that this Rehbinder effect does not occur in metal cutting when the whole of the cutting zone is flooded with lubricant and suggests, paradoxically, that Rehbinder, who used flood lubrication in his metal-cutting studies, could not have observed the effect in metal cutting which bears his name.

Fatigue Crack Propagation in Metals

A PARAMETER often used for correlating the propagation rate of fatigue cracks is the stress intensity factor K. This follows the work of Irwin[1], who showed that the elastic stresses at a point near the root of a crack always have the form

$$\sigma = \frac{K}{\sqrt{2r}} f(\theta) \quad (f(\theta) \leqslant 1)$$

where r and θ are polar co-ordinates, with the origin at the crack tip, of the point. The expression is only valid if $r \ll a$ (the crack half length).

This report provides K values for crack propagation rates of 10^{-5} and 10^{-4} in. per cycle obtained from fatigue experiments on various metals—the object being to try to correlate the K values for fixed crack propagation rates with the tensile properties of the metals. Most of the experiments were made on test pieces of $\frac{1}{2}$ in. × 1 in. cross-section tested in bending, the K values being calculated from the measured bending moments using the boundary collocation calculations of Gross and Srawley[2]. Table 1 gives the K values and includes some values obtained from tension experiments on panels 3 in. wide. (Experiments on specimens cut from the same sheet of *D.T.D.*5070 aluminium alloy gave very good agreement when tested in either tension or in bending.) The loading in the fatigue experiments was of the form $1{\cdot}1\ P \pm P$ (stress at the crack tip always tensile) and the K values were calculated from the alternating load (P) rather than the peak load ($2{\cdot}1\ P$) which is sometimes used. Table 1 also gives the tensile properties of the metals and values of K/E, where E is Young's modulus. It will be seen that the K values for the two propagation rates do not correlate with the tensile properties of the materials but that the values of K/E are reasonably constant. When log K/E is plotted against log da/dn a straight line of slope 3·6 is obtained and over the range investigated ($da/dn = 10^{-6} - 10^{-4}$ in./cycle) a reasonable approximation to the fatigue crack propagation rate for all the metals is given by the equation

$$\frac{da}{dn} = 3{\cdot}43 \times 10^{7} \left(\frac{K}{E}\right)^{3{\cdot}6} \qquad \begin{pmatrix} K \text{ in lb./in.}^2 \times \sqrt{\text{in.}} \\ E \text{ in lb./in.}^2 \end{pmatrix}$$

This suggests that the main factor governing the propagation rate of fatigue cracks is the elastic strain concentration at the tip of the crack and not the flow properties of the metals as might be expected. It should be noted that the experimental values were obtained from tests made in laboratory air so that it is possible that in some cases the low values of K/E resulted from the rate of crack propagation being accelerated by corrosion fatigue.

Another point to be considered is the effect of frequency on fatigue crack propagation. It has been shown by Schijve, Broek and de Rijk[3] and by Bradshaw and Wheeler[4] that for aluminium alloys a change of frequency of 100 to 1 produces a change in the propagation rate of fatigue cracks of about 1 to 2. This is probably a corrosion fatigue effect because for tests on aluminium alloy *in vacuo*[4] the same change in frequency produced a much smaller change in the rate of crack propagation. It seems, therefore, that in the absence of corrosion the propagation rate of fatigue cracks is not influenced to any great extent by the time during which the stress is applied.

From fractographic studies of fatigued surfaces it has been shown by Forsyth and Ryder[5] and by Schijve[6] that at high propagation rates ($> 10^{-3}$ in./cycle) the crack advances every stress cycle, and recent work by Hertzberg[7] indicates that this relation holds for crack propagation rates as low as 10^{-6} in./cycle. It seems therefore that once the cracking process has started it repeats itself every cycle.

The implications of these considerations are that for the propagation of fatigue cracks a metal can be regarded as a continuum in which the rate at which the crack advances is governed by the geometry of the system and the distribution of elastic strain near the crack tip. It is well known that a plastic zone forms ahead of the crack during fatigue cycling before failure occurs, so plastic flow would have to be taken into account in any mathematical treatment of the problem.

A possible qualitative mechanism by which the crack grows will now be suggested. Once a crack has formed, probably by a dislocation mechanism, the highly strained material at the end of the crack flows to form a plastic zone in front of the crack. Eventually, owing to restraint by the surrounding material a condition of triaxial tension is reached in a small region at the crack tip. In this region the shear stress is less than that required to cause flow and a large elastic tensile strain can occur. The material fails in tension and the crack advances until the strain is relieved by plastic flow in the surrounding material. Reverse flow occurs in the plastic zone as the stress is removed and during the next cycle the condition of triaxial tension again occurs, the material fails and the crack advances. It seems probable that this process can

A System of Nomenclature for the Fibrous Calcium Silicates, and a Study of Xonotlite Polytypes

FIBROUS calcium silicates occur as polytypes because each $(Si_3O_9)_\infty$ or $(Si_6O_{17})_\infty$ chain can occupy alternative positions differing by $b/2$ relative to sheets of calcium atoms[1–7]. In an attempt to limit the number of "trivial" names, the International Mineralogical Association's Commission on Mineral Names[8] has recommended the use of suffixes such as wollastonite-Tc and -2M, but cases with several variable parameters were not adequately covered. This communication describes a comprehensive system of nomenclature, which uses suffixes derived from the reciprocal lattice. This system could be extended to cover polytypes in other inorganic phases.

Diffraction patterns from polytypes of any species of calcium silicate have certain reflexions in common, which indicate a "pseudo-cell" corresponding to the repeat unit for the calcium and most of the oxygen atoms. Weaker, often streaky reflexions are also present, associated with the positions of the silicate chains. A smaller reciprocal cell in accord with the weak reflexions can be defined on the same axes as the reciprocal pseudo-cell, as in Fig. 1. A suffix $LUVW$ is then allocated to define the polytype, so that Ua^* = pseudo-a^*, Vb^* = pseudo-b^* (V is almost invariably 2), and Wc^* = pseudo-c^*; U, V and W are also the ratios between the true and pseudo-repeat distances along the pseudo-cell axes in the real lattice. The prefix L represents the Bravais lattice type (P, C, A, F or I), and indicates translational relationships between adjacent pseudo-cells. The usual conventions for selecting the true unit cell are ignored, as they would obscure the relations between polytypes, but a more conventional unit cell may be selected later if required. On the proposed system, wollastonite-Tc and -2M would be renamed wollastonite-C221 and -P121, respectively, and the two known polytypes of foshagite, $Ca_4Si_3O_9(OH)_2$ (ref. 7), would bear the suffixes A122 and F222.

Xonotlite, $Ca_6Si_6O_{17}(OH)_2$, is a typical fibrous calcium silicate, comprising triple rows of calcium atoms, double silicate chains, and hydroxyl ions[2,3]. Consideration of the structure suggests the possibility of four regular polytypes, xonotlite-P121, -C221, -A122 and -F222, and two others, -P∞21 and -A∞22, with complete disorder within (001) planes. Reciprocal lattices for these polytypes are shown in Fig. 1. Earlier I used electron diffraction to identify xonotlite-A122 in a specimen from San Francisco[9]. A specimen stage for the electron microscope permitting tilt through angles up to 55° about any selected axis has recently been used to investigate polytypes in samples from four other localities, in Newfoundland, Puerto Rico, Pakistan and Aberdeenshire, Scotland. Six synthetic specimens have also been examined; they were prepared hydrothermally at temperatures of 165, 185, 200° C (ref. 10), and 350° C (Dr. K. Speakman), for times between 25 and 120 h. The Aberdeenshire specimen comprised A122, F222, A∞22 and P∞21 polytypes, and intergrowths with values of 1 and 2, or 2 and 4, for W. All the other natural crystals were A122 or A∞22 types. Synthetic specimens prepared at 165° and 185° C were all A∞22, but the higher preparation temperatures favoured intergrowths of A∞22 with P121 or P∞21. Reflexions with $W = 1$ were stronger than for $W = 2$ in the 350° C specimen.

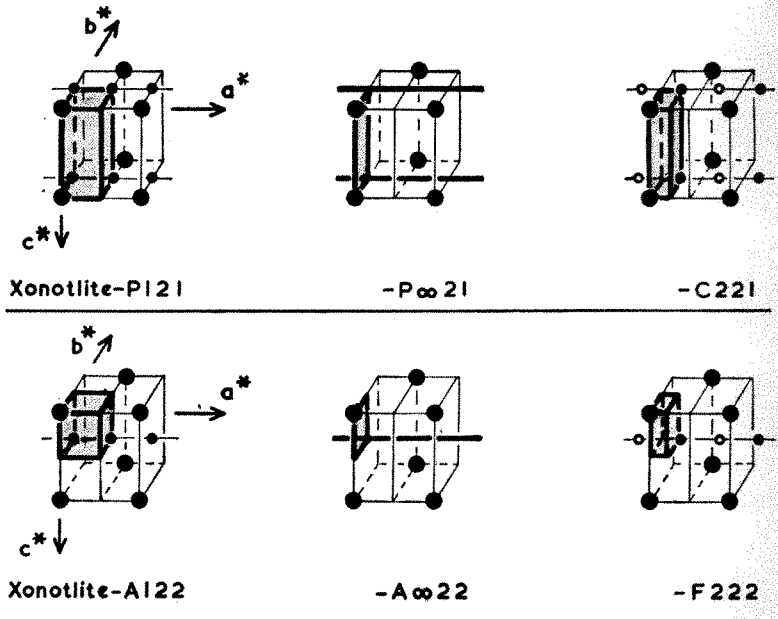

Fig. 1. Reciprocal lattices for polytypes of xonotlite, with their symbols on the proposed system of nomenclature. For the polytypes in the upper half, c is not doubled, that is, $W = 1$, while for those in the lower half, c is doubled, and $W = 2$. Reciprocal pseudo-cells are outlined in thin lines; the true reciprocal cells defined on the same axes are outlined in thick lines and shaded. For polytypes C221 and F222, small closed and open circles represent reflexions for the twinned forms.

Completely ordered polytypes were observed in natural crystals only for $W = 2$, and in synthetic crystals only for $W = 1$. The temperatures of formation of the natural specimens are not known, but the Aberdeenshire specimen, which contained P∞21 polytype, occurred in a metamorphic region, with considerable evidence of high-temperature products. The results therefore suggest the possibility of a low-temperature xonotlite with $W = 2$, and a high-temperature form with $W = 1$. Consideration of the central row of calcium atoms, in each triple row parallel to b, shows that each calcium has one hydroxyl ion co-ordinated where $W = 2$ while two and no hydroxyls alternate where $W = 1$. Taylor and I have shown[7] that similar rows of calcium atoms in foshagite have equal co-ordination of hydroxyl ions, possibly because of forces owing to the relative polarizations of Ca—OH and Ca—OSi bonds. The present investigation suggests that such forces may be dominant at lower, but not at higher, temperatures of formation for xonotlite. In order to test this hypothesis, samples of xonotlite will be prepared with very long reaction times at various temperatures, and data on the natural localities will be examined for evidence of formation temperatures.

I thank Prof. H. F. W. Taylor, Dr. A. Aitken, Dr. K. Speakman, and Dr. H. G. Macpherson for the specimens of natural and synthetic xonotlite, and for their interest in this work.

PHYSICS

Piezoelectric Effect in Poly-γ-methyl-L-glutamate

THIS communication presents some experimental evidence illustrating the piezoelectric effect in certain synthetic polypeptides.

It has been recently established that a number of high polymeric substances show a piezoelectric effect[1,2]. The substances so far investigated have been naturally occurring polymers such as cellulose, keratin, silk fibroin and collagen. Actual specimens used in the study have been taken from wood[3-5], wool[6], silk[7], bone[8-10] and tendon[11].

The effect can be accounted for by taking into consideration the crystal symmetry and unidirectional orientation of crystallites of such polymers. It seems likely that the origin of piezoelectricity in cellulose and protein results from the abundance of hydrogen bonds in their crystal structure. Until now, the piezoelectric effect in synthetic polypeptides—in which the hydrogen bond plays an essential part in determining its molecular configuration and crystal structure—has not been investigated.

Thin films of poly-γ-methyl-L-glutamate were kindly provided by the Ajinomoto Chemical Co., Tokyo. The film was stretched to twice its original length, and this resulted in a thickness of about 0·025 mm. The electrodes, each with a diameter of 10 mm, were fixed on either side of circular films of 20 mm diameter by painting them with silver paste. One end of the film was clamped to a small metal bar connected to the centre of an electromagnetic vibrator and the other to a frame which could be adjusted so as to give an appropriate tension to the film. Through two thin, flexible silver foils attached to the electrodes, the electric signal was led to a differential amplifier and then to a synchroscope.

If a longitudinal vibration was applied to the film by the electromagnetic transducer, an electrical polarization with the same frequency as that of the mechanical vibration was produced on the faces of the film and could be presented on the vertical axis of the synchroscope. If a voltage proportional to the coil current in the electromagnetic transducer was applied to the y axis of the synchroscope, a Lissajous figure, showing the relationship between stress and polarization of the specimen, was observed. During measurement, the circular film was rotated to various angles to the oriented direction so that the stress could be applied in different directions.

The apparent piezoelectric modulus d, which is the coefficient connecting the electrical polarization and mechanical stress, is plotted in Fig. 1 against the angle θ between the direction of stress and the orientation axis. The points are the average of experimental results for two films. The curve is well represented by a formula $d = d_{max} \sin 2\theta$, as would be expected for such unidirectionally oriented substances. The absolute value of the piezoelectric modulus d_{14} for these films of poly-γ-methyl-L-glutamate is $2{\cdot}8 \times 10^{-8}$ C.G.S.E.S.U., which is about half the d_{11} coefficient of quartz crystal.

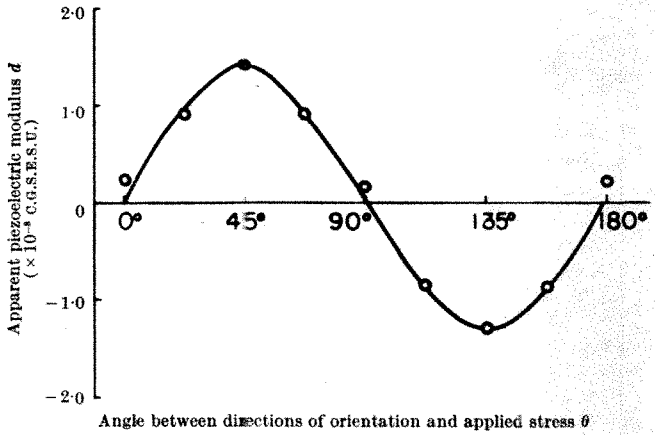

Fig. 1.

It is significant that the value of piezoelectric modulus is fairly large. This substance does not absorb water because methylation of the acidic group occurs. The molecular conformation is the α-helix form. The degree of polymerization is 3,200. The degree of crystallinity is unknown, but would be higher than 30 ~ 40 per cent, as roughly estimated by X-ray diffraction patterns. It is believed that many synthetic polypeptides other than poly-γ-methyl-L-glutamate will also show a similar piezoelectric effect and that such studies might provide fundamental clues toward understanding the piezoelectric effect observed in a number of biological substances such as hair, bone and tendon.

Potentials of Metallic Powder Formation on the Mercury Dropping Electrode

THE formation of electrolytic metallic powders on solid electrodes at a certain potential in the region of the limiting current was first observed with copper, gold and cadmium[1,2]. However, the conditions of electrodeposition on the solid electrodes make it impossible to determine precisely the corresponding potentials[3] and to construct a series of potentials of metallic powder formation.

Using the phenomenon of metallic dendrite formation on the dropping mercury electrode[4], it is possible to determine the potential of the powder formation with a relatively high precision (±25 mV) by microscopic observation. In the case of cadmium, for example, the powder begins to form at a potential more negative than −0·9 V (Fig. 1). At the same time the concentration of the metal ion must be greater than a certain minimum value (0·0125 M for Cd^{2+}). In this way we determined the series of potentials of formation (ε_p) of various metallic powders on the mercury dropping electrode (Fig. 2). Fig. 2 shows that these potentials are independent of the concentration and that the minimum value is in general about 0·01 M. Experimentally it was found that the formation of powders is favoured by a certain value of the rate of growth of the surface of the drop. In the case of cadmium, in a range of concentration of 0·1–0·4 M, the metallic dendrites are formed when a fast capillary (t_1 = 3 sec) is used, while in the range of 0·025–0·05 M it is necessary to use a slow capillary (t_1 = 75 sec). The presence of gelatine favours the dendrite formation by diminishing the threshold of the concentration. The experimental observation shows also that the dendrites are not in close contact with the mercury; immediately after direct contact with mercury is established, the particles are rapidly dissolved in the mass of the drop and often (in the case of the cadmium, for example) an intense hydrogen discharge is observed on the non-dissolved dendrite portions.

These experimental results are in good agreement with the quantum mechanical mechanism suggested for the formation of electrolytic metallic powder[1,3] and make possible a more complete explanation of the phenomenon.

Nucleation of the Solid Phase by Cavitation in an Undercooled Liquid which expands on Freezing

HICKLING[1] has proposed that nucleation by cavitation in an undercooled liquid which expands on freezing is caused by adiabatic compression into a region where a high pressure phase is stable: the high pressure phase nucleates and later transforms to the stable low pressure phase. Originally, his arguments were intended to explain only the results on water, but were later extended to include other materials which expand on freezing[2], although no such observations were available.

In recent experiments we have found that gallium, which expands on freezing, behaves like water, benzene, nickel, etc., in that the solid phase can be nucleated

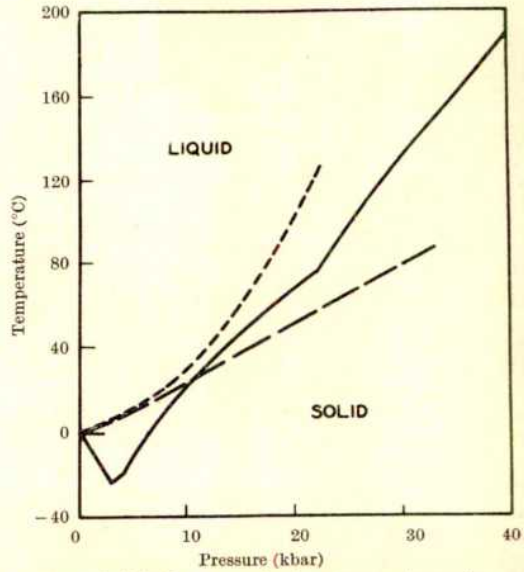

Fig. 1. Lines of adiabatic compression in water superimposed on a plot of the equilibrium melting line of ice. — —, Reversible adiabatic compression. - - -, Shock-wave adiabatic compression.

in the undercooled liquid by cavitation. A 2 c.c. sample of gallium contained in a sealed glass tube could be undercooled 25° (to 5°C) but nucleated in an ultrasound field with a few degrees undercooling. We believe that this is the first observation of such nucleation in a material other than water which expands on freezing.

In calculating the path taken during the collapse of a cavity, Hickling has considered only the temperature rise which results from reversible adiabatic compression. The collapse of a cavity is not reversible in the thermodynamic sense. The conditions should more closely approximate those in a shock front, as specified by the Rankine-Hugoniot[3] relationships. Using these equations we have calculated the irreversible part of the heating under such conditions[4]. This gives the temperature rise as indicated by the dotted line in Fig. 1. It is evident that the irreversible heating is sufficient so that the high pressure solid phase will not nucleate, because the liquid phase is stable over the entire path. The mechanism suggested by Hickling cannot, therefore, be operative in water. The nucleation must occur while the system is locally under tension, as has been suggested by Hunt and Jackson[4].

Effect of Precipitation on Transmission through the Atmosphere at 10 Microns

THE development of high power maser sources at 10·6 microns[1] has made possible an investigation of the characteristics of propagation through the atmosphere at this wavelength. Our investigations were conducted over the same 2·6 km path in Holmdel, New Jersey, which was used at shorter wavelengths by T. S. Chu and D. C. Hogg[2].

A continuous gas-flow 10·6μ oscillator, provided by T. J. Bridges[3] and operated to produce 0·5 W, was used as the source in our experiments. Observations were made continuously during most of the period from December 1965 to the end of May 1966. The 7 mm diameter output beam of the maser was directly transmitted during most of the work, although a 6 in. diameter Cassegrainian telescope was also used. The receiver was a thermopile placed at the focus of a 6 in. mirror. Mechanical chopping of the transmitted beam at 10 c/s and synchronous detection yielded a measuring range between 50 and 70 dB depending on the configuration used.

Fogs. During the past North American winter on ten occasions—each lasting several hours—we observed attenuation, due to fog, larger than our measuring range. On one such occasion we observed a fade of 50 dB which lasted a few minutes and which we were able to correlate with the movement into the beam of a patch of fog which intercepted less than half the 2·6 km path when the attenuation was maximum.

Snow. Because theoretical predictions of snow attenuation at different wavelengths have not so far been possible, it was of particular interest to observe the wavelength dependence of this effect. On six occasions during the past winter, appreciable snowfalls occurred and in each case there were periods, typically several hours long, during which the attenuation exceeded 50 dB. On one such occasion, simultaneous measurements were made by T. S. Chu at 0·63μ and 3·5μ. A comparison of the data indicates that the attenuation in decibels at 10μ was about 50 per cent greater than at the shorter wavelengths.

Rain. Most of the appreciable rainfalls during this period were accompanied by light fogs which produced the dominant attenuation and, therefore, obscured the effects resulting from the raindrops. On three occasions, however, rainfalls essentially free of fog were recorded. The attenuations observed were all between 8 and 10 dB/mile/in./h precipitation rate. (The rates measured ranged up to 2 in./h.) This result can be compared with the theoretical prediction of 11·5 (in the same units) by Chu[4]. Because this theory does not take into account the fact that some of the forward scattered signal is collected by the receiver, we consider the agreement between theory and experiment to be quite good.

We thank T. J. Bridges and T. S. Chu for their co-operation in this experiment.

Variable Focal Length Lenses using Materials with Intensity Dependent Refractive Indices

RECENT theory[1–3] and experiments[4–7] have demonstrated the existence of an intensity dependent non-linear component in the refractive index of some materials. This non-linearity in the refractive index has been observed to rotate an elliptically polarized optical maser beam[4,5] and to lead to self trapping[6,7]. This communication considers the two step nature of focusing which leads to the conclusion that a sample tank filled with one of these non-linear materials can be made to behave like a lens. It will be shown that it is possible for beam trapping to occur within the non-linear medium but for the beam to come to a focus outside the medium tank (see Fig. 1).

Consider, for example, a diffraction limited beam of the form

$$E^2 = \frac{8\pi^2 a^2 \eta_0}{c\lambda^2 R^2} P_t \left\{\frac{2J_1(ka\beta)}{ka\beta}\right\}^2 \qquad (1)$$

where a is the radius of the aperture, λ is the free space wavelength of optical maser, η_0 the refractive index, c the velocity of light, R the distance from aperture, P_t the total beam power, $J_1(ka\beta)$ the Bessel function, and $\beta = \sin\theta$. If the non-linear refractive index is of the form

$$\eta_1 = \eta_0 + \eta_2 E^2 \qquad (2)$$

then the non-linear portion becomes

$$\eta_2 E^2 = \frac{8\pi^2 a^2 \eta_0 \eta_2}{c\lambda^2 R^2} P_t \left\{\frac{2J_1(ka\beta)}{ka\beta}\right\}^2 \qquad (3)$$

From equations (2) and (3) it is obvious that the refractive index is not uniform across the beam owing to the power distribution in the beam. This means that the centre of the beam will be slowed more than the edges as shown in Fig. 1. The net result of this non-uniform phase delay across the beam is identical to what occurs in a lens as a result of the increased path length in the centre of the lens. If the same considerations are used here as in the case of thick lenses it is possible to determine an effective focal length for our non-linear system.

When the phase delay between the outer edge and the centre of the beam is computed for passage of the beam a distance ΔR in the tank, the effective difference in path

length between the centre and the extremal rays is shown to be

$$\Delta l = \frac{8\pi^2 a^2 \eta_2}{c\lambda^2} P_t \left(\frac{\Delta R}{R_0 (R_0 - \Delta R)} \right) \quad (4)$$

Substituting for Δl using the Sagitta equation

$$\Delta l = \frac{a^2}{2R_0}$$

the distance in the sample tank at which self-trapping occurs (that is, the beam is rendered parallel) is seen to be

$$\Delta R = (1{\cdot}64)\eta_0 a^2 \left[\lambda + \frac{16\pi^2 \eta_2}{c\lambda} P_t \right]^{-1} \approx \frac{0{\cdot}103\, \eta_0\, c\lambda\, a^2}{\pi^2 \eta_2 P_t} \quad (5)$$

Thus equation (5) gives the minimum path distance necessary to render the diverging diffraction limited beam parallel. If the path length in the tank is further increased, the beam will necessarily converge and focus outside the tank. As the tank length is increased the focal point moves toward the tank-air interface and for a distance in the medium beyond ΔR of R_f given by

$$\delta R = R_f = \frac{a^2 \eta_0}{3{\cdot}8} \sqrt{\frac{c\eta_0^2}{\eta_2 P_t}} = a^2 K \quad (6)$$

(which is very nearly what Kelley[3] obtained) the beam will focus in the tank. Thus it is seen that it is possible for the beam to focus outside the tank for a tank length l between

$$\Delta R < l < \Delta R + R_f \quad (7)$$

With these ideas in mind it is now possible to determine the relationship between the focal length of the non-linear system and the tank length l. Because

$$\delta R = l - \Delta R \quad (8)$$

it is obvious that the radius of the beam at the air-tank interface is given by the relationship

$$\rho^2 = \frac{a^2 K - \delta R}{K} \quad (9)$$

Furthermore, the path difference between the extremal and the central ray of the beam is

$$\Delta l = \frac{4{\cdot}9\pi^2 \eta_0 \eta_2}{\lambda c} P_t \left\{ 1{\cdot}64 \frac{a^2}{\lambda \delta R} + 1 \right\}^{-1} \quad (10)$$

Using the Sagitta equation again, the focal length is found to be given by the relationship

$$f' = \frac{\rho^2}{2\Delta l} \quad (11)$$

This must, however, be modified because there is a change of index of refraction at the tank-air interface. The focal length of the system thus becomes

$$f = \frac{f'}{\eta_0} = \frac{a^2 K - \delta R}{2\eta_0 K \Delta l} \approx \frac{a^2 K - l}{2\eta_0 K \Delta l} \quad (12)$$

the approximation being valid as $\Delta R \approx 0{\cdot}05\, R_f$.

A theoretical focal distance has been calculated for a 10 cm length tank l filled with carbon disulphide, an input beam power P_t of 100 kW and an aperture diameter of 0·5 mm. From ref. 5, η_2 is found to be $3{\cdot}1 \times 10^{-11}$ E.S.U. at a λ of 6943 Å. From equation (12), the focal length f is thus found to be 18·5 cm.

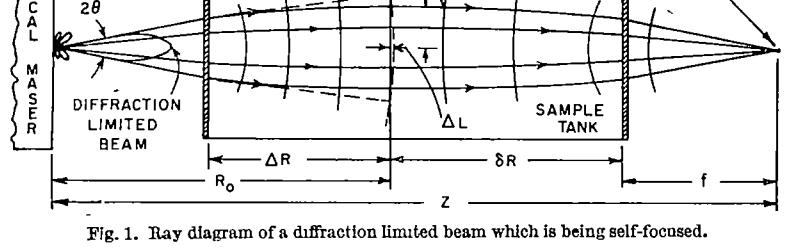

Fig. 1. Ray diagram of a diffraction limited beam which is being self-focused.

It should be pointed out at this time that in this crude analysis only the centre and extreme rays have been considered in arriving at the focal distance of equation (12). For a complete analysis all intermediate rays should be considered, which would yield the spherical aberration of the system. It will turn out that the spherical aberration is dependent on the beam intensity profile and would be different for a Gaussian distribution than for an aperture limited distribution. Thus it is that this lens in general has a tendency for spherical aberrations; however, it should be possible to select a beam profile such that no aberration occurs. It should also be noted that the focal point of equation (12) is dependent on both power and frequency owing to the dependence of f on P_t, λ and $\eta_2(\omega)$.

CHEMISTRY

New Evidence for the Fine Structure of Porous Carbons

Most speculations about the detailed pore structure of carbons have been unsupported by direct experimental evidence. The classification in terms of micropores, transitional pores and macropores was developed mainly by Dubinin *et al.*[1] on the basis of adsorption and mercury penetration investigations. These methods, however, give no information about the detailed pore geometry and only limited information about the statistical character of the structure. Molecular sieve investigations[2] have led other workers to the conclusion that the pores are often slot-like. Wolff[3] and Mizushima[4] have proposed more specific models in which active carbons are pictured as aggregates of graphite-like plates which impose a slot-like character on the spaces between them.

We have obtained evidence, based on a combination of adsorption and electron microscopic investigations, which enables us to propose a more complete structure for carbons produced by the decomposition of powdered or pelletted polyvinylidene chloride (PVDC): the same model is thought to be applicable to carbons formed by the decomposition of hexaiodobenzene, coconut shell and anthracite coal.

When the initial stages of the decomposition of PVDC occur below the softening point of the polymer (~180° C) the morphology of the original polymer sets the pattern for the structure of the carbon. Once about 10 per cent of the decomposition has taken place at the lower temperature, the nature of the final carbon is insensitive to the conditions under which the reaction is completed. In the present work, carbons ("low-temperature" chars) were prepared by carrying out about 50 per cent of the decomposition below 180° C, and completing decomposition

(100 ± 0·2 per cent) by raising the temperature to 750° C.

Adsorption of benzene at 25° C by low temperature PVDC chars is accompanied by a hysteresis loop extending from the saturation vapour pressure down to a relative pressure of about 0·25 (Fig. 1*a*, *d*). When samples of such chars are finely ground (to pass 400 B.S.S. sieve size) the powder retains its high adsorptive capacity, but the hysteresis loop is largely and sometimes completely eliminated (Fig. 1*a*, *d*): similar results (though not always leading to complete elimination of hysteresis) have been obtained with carbon prepared from hexaiodobenzene decomposed below its melting point (Fig. 1*b*), with coconut shell charcoals (Fig. 1*c*), and with anthracite coal charcoals. Soft coal charcoals, however, still retain a hysteresis loop after grinding.

Electron microscopic examination of finely ground low temperature PVDC chars shows that they consist very largely of thin platelets (200–500 Å thick) of carbon the porosity of which is too fine to be observed. These observations are consistent with the view that the carbon platelets have been formed from polymer crystallites. A detailed investigation of ultrasonically dispersed samples of the PVDC powder from which our carbons have been prepared shows that they are highly crystalline. Although a variety of habits have been observed, typical crystals are of the order of 100 Å thick and occur as sheets, or more often as ribbons (possibly formed by rupture of the sheets in preparing the samples for electron microscope investigation) 2–3μ wide and 30μ or more long. The carbon particles formed by pyrolysis are usually thicker than the single polymer crystals: multi-layer crystals in the original polymer, which are broken down by ultrasonic dispersion, are probably bonded together during the cross-linking stage of the decomposition.

The major part of the adsorptive capacity of the final carbon is associated with the very fine and extensive micropore structure of the pseudomorphs of the original polymer crystals. These pores are formed by the loss of hydrogen chloride from the crystals: on the basis of the folded chain picture of polymer crystals[5], one would expect

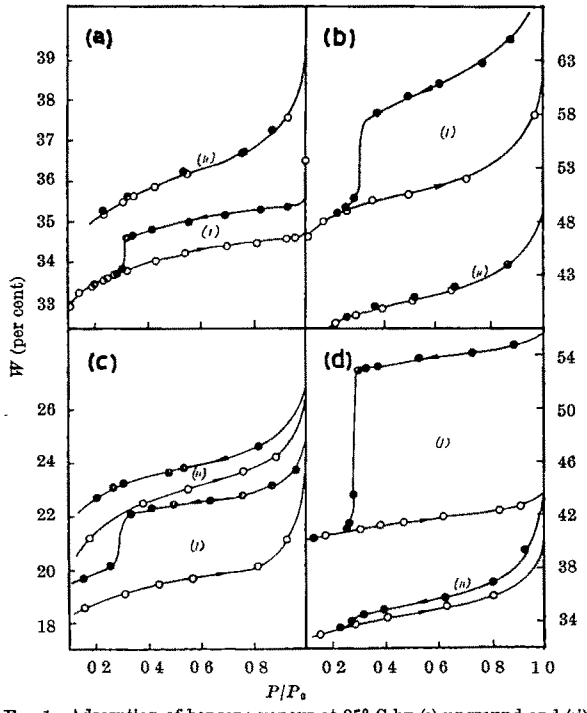

Fig. 1. Adsorption of benzene vapour at 25° C by (i) unground and (ii) finely ground samples of. *a*, carbon from decomposition of PVDC powder (sample *B*9-1077 from Dow Chemical Company) pelletted at 75,000 lb./in²; *b*, carbon from hexaiodobenzene decomposed below its melting point; *c*, activated coconut shell charcoal; *d*, carbon from decomposition of PVDC powder (sample *EP*-961-10-9 from Dow Chemical Company) unpelletted ○, Adsorption; ●, desorption.

these pores, generally, to be oriented normally to the crystal surface. They are of molecular dimensions, and consideration of the stereochemistry of the cross-linking reactions which are needed to complete the decomposition makes it plausible that they should have a slot-like character: this structure occurs within the platelets. The stacking together of these porous crystal pseudomorphs forms a second structure of voids with which the capillary condensation hysteresis is associated. The elimination of hysteresis by breaking down the void structure by grinding is essentially the converse of the experiments of Carman and Raal[6], who were able to create void structures and so to induce hysteresis of this kind by pelletting fine non-porous silica and carbon black powders. The similarity in the response to grinding of hexaiodobenzene carbons, coconut shell charcoal, and anthracite charcoals suggests that these materials have a structure similar to that already described: work to confirm this is in hand. In each case the nature of the starting material and its observed behaviour during carbonization make it probable that the basic crystal structure is retained in the carbonization process, although the random nature of cross-linking reactions destroys the regular internal structure so that the carbons show no clearly distinguishable X-ray patterns.

Carbons formed by the decomposition of PVDC above its softening point, of hexaiodobenzene above its melting point, or of PVDC in solution, exhibit small or vanishing hysteresis loops in benzene adsorption and electron micrographs show them to have a much more uniform dispersed structure apparently formed by the decomposition of amorphous material. The PVDC chars prepared by Wynne-Jones *et al.*[7] from the glassy polymer obtained by exposing liquid vinylidene chloride to sunlight show no hysteresis and presumably also have a similar structure.

These views are supported by further work on PVDC polymers the softening point of which has been raised by ultra-violet irradiation or by flash photolysis; and on PVDC/PVC copolymers with lower softening points. They are also consistent with the results of an investigation of the kinetics of the decomposition of these polymers.

Losses due to Adsorption during Filtration of Aqueous Solutions of Polycyclic Aromatic Hydrocarbons

Although it has been pointed out that some adsorption of a solute may occur during filtrations[1] there is apparently no general awareness of the possible magnitude of such losses with dilute solutions of certain solutes. Loss by adsorption of polycyclic, aromatic hydrocarbons during filtration[2] or dialysis[3] has been mentioned briefly, and such adsorption has been shown[4] to be the cause of a major discrepancy in some recent attempts to determine the solubilities of such hydrocarbons in aqueous solutions of deoxyribonucleic acid (DNA)[3,5–7]. Stauff and Reske[8] found filtration to be unsuitable for the removal of benzo[*a*]pyrene in determinations of solubility in aqueous protein solutions; they attributed the observed 20–50 per cent error to mechanical denaturation of the protein

by the glass frit during filtration, but it is quite possible that adsorption of the hydrocarbon was also a contributing factor. Except for a brief investigation of the amount of protein adsorbed during the filtration of aqueous solutions through 'Millipore' filters[9], however, there has been no detailed report on the extent of losses due to adsorption.

In the course of some preliminary experiments on solubilization undertaken 3 years ago, I was able to trace the erratic results obtained for the solubilities of pyrene and benzo[*a*]pyrene in aqueous solutions of polyvinylpyrrolidone (PVP) or DNA to adsorption of the hydrocarbons by the filter media.

To evaluate the extent of this adsorption, experiments were carried out on solutions of phenanthrene in distilled water, because phenanthrene is sufficiently soluble in water to permit changes in concentration to be observed spectrophotometrically by means of the strong absorption band at 251 mμ. To reduce errors arising from the background absorption resulting from ultra-violet absorbing materials leached from the filters and from light-scattering by suspended particles, the base-line technique[10,11] was used for determinations of concentration. It is especially important to use this method in solubilization experiments if the solvent is a solution of a polymeric material. The solute often appears to bring about changes in the light-scattering and sedimentation properties of the polymer, with the result that the background absorption of the reference blank and the experimental solution are no longer exactly comparable. (Application of the base-line technique to the spectral curves shown in Fig. 3 of ref. 7, using readings at 385, 395 and 405 mμ, indicates that the concentrations of benzo[*a*]pyrene actually remain quite constant at about 1×10^{-6} M during centrifugation. The spectral changes shown in this figure appear to be the result of the more rapid sedimentation of the DNA in the hydrocarbon-containing solution than in the blank[3]. I have also observed a similar effect in PVP solutions of these hydrocarbons.) All spectrophotometric measurements were made on a double-beam recording spectrophotometer using matched, fused quartz absorption cells with the appropriate solvent or solution as a reference. The results obtained are shown in Table 1.

The solutions used were filtered solutions which showed no particles of undissolved phenanthrene when examined visually in ultra-violet light[12]. A membrane filter (solvent-resistant; pore size 0·45μ) was the material usually used for this preliminary filtration. No essential difference in the amount of phenanthrene adsorbed was observed when suspensions were used instead of pre-filtered solutions. Comparable results were also obtained when aqueous solutions of naphthalene, pyrene or anthracene were filtered, and the relative losses were greater with the less soluble hydrocarbons. For example, when an aqueous solution of pyrene was filtered through a sintered glass filter (fine frit) the concentration of pyrene in the first 50-ml. portion of filtrate was 44 per cent of the original concentration. Similarly, no anthracene could be detected spectrophotometrically in the final 20 ml. portion of filtrate after filtration of 270 ml. of an aqueous suspension of anthracene through 'Polypore *AM*-7'. No adsorption of hydrocarbon was observed from solutions in aqueous ethanol (20 or 50 per cent) or in other organic solvents. When solutions of pyrene, benzo[*a*]pyrene, benz[*a*]anthracene, dibenz[*a*,*h*]anthracene, or similar hydrocarbons in aqueous solutions of PVP or DNA were filtered there was a marked loss of hydrocarbon in the filtrate.

For several hydrocarbons, particularly with the membrane filters, some of the adsorbed hydrocarbon could be washed out of the filter with a small amount of water after the filter had been allowed to dry. Occasionally, supersaturated solutions were obtained in this way. Most of the adsorbed hydrocarbons could be washed out of alcohol-resistant filters with ethanol.

Such polymeric materials as PVP and DNA were also adsorbed from aqueous solution, but the filters were quickly saturated by these materials and, after the first 20–50 ml. of filtrate had been collected, further changes in concentration of the filtrate were not usually observed. In contrast to this rapid saturation, and the saturation of membrane filters by protein[9], the filters are not readily saturated by the hydrocarbons. Even after filtration of sufficient solution to give apparent saturation, refiltration through the same filter often produced a further reduction of the concentration of hydrocarbon in the filtrate.

From Table 1, it may be seen that the amount of hydrocarbon removed from solution by adsorption during filtration depends to some extent on the composition of the filter, but that the pore size of the filter also has a very marked effect, indicating the influence of changes in surface area as well as in the rate of filtration. The pronounced increase in the amount of hydrocarbon removed from solution when two filters are used instead of one (see the data obtained with 'Polypore 27*A*') is also a result of increased surface area and decreased rate of flow. The effect of changes in the rate of filtration alone may be seen particularly well in the data for 'Polypore *AM*-1' and 'Polypore *GM*-6', where a decrease in the rate of filtration resulted in a sharp decrease in the concentration of phenanthrene in the filtrate.

Munck[13] used silicone-treated glassware to reduce the adsorption of steroids from aqueous solutions; but, in the present work, similar treatment of fritted-glass filters with a silicone preparation did not produce any clear-cut effect on the amount of phenanthrene adsorbed during filtration. The reduced affinity of the treated surface for

the hydrocarbon appears to be counteracted by the effect of the reduction in the rate of filtration brought about by the hydrophobic surface of the filter.

In addition to the errors introduced by this adsorption during filtration, particles of hydrocarbon (seen as bright fluorescent specks when the filtrates are viewed in ultraviolet light) occasionally pass through paper or sintered-glass filters. The centrifugation procedure of Kofahl and Lucas[14] was found to give fairly reproducible results, even with viscous solutions of highly polymerized DNA. Two centrifugations, with 'Pyrex'-wool plugs centrifuged down on to the residue, were sufficient to ensure removal of suspended hydrocarbon. Comparison of the spectra of the resulting solutions and of the original suspensions, using the base-line technique, showed the change in concentration of the dissolved hydrocarbons to be less than 10 per cent during this procedure. By this method, considerably less variation is observed than when filtration is used to remove undissolved hydrocarbon. The loss may arise from adsorption on the centrifuge tubes and on the glass-wool plugs.

This work was supported, in part, by the Division of Air Pollution, U.S. Public Health Service, Department of Health, Education and Welfare. I thank Dr. H. S. Isbell, Dr. R. S. Tipson and J. H. Gould for helpful discussions.

X-ray Fluorescence Analysis of Heavy Elements in a Light Matrix

WHEN solids or liquids are irradiated with X-rays the elements in the substance emit secondary fluorescent radiation. The intensity of the fluorescent radiation from an element in a mixture is usually not proportional to the concentration of that element. The reason for this is that the heavy element exhibits an X-ray absorption markedly different from the matrix. Thus a plot of the intensity of the emitted wavelength (L line) against concentration of the heavier element in the mixture gives a curve which, as the concentration of the element increases, becomes parallel to the concentration axis (Fig. 1L).

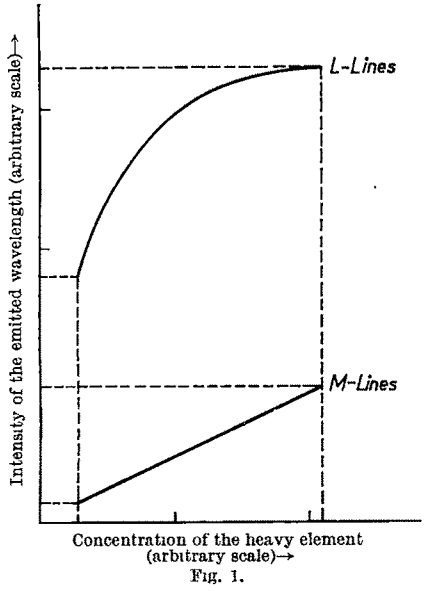

Fig. 1.

Addink, Kraay and Witmer[1] have shown that by adding quantities of strongly absorbing material, a linear relationship can be effected between the intensity and concentration; however, special considerations are required when the results so obtained are interpreted. The same effect can be accomplished by making intensity measurements at a longer wavelength when the absorption in the heavy element and matrix is more or less equal (Fig. 1M). Under these conditions, the analysis resembles the measurement of the concentration of a light element in a light matrix. Thus, for example, when the concentration of lead in silicates is determined by this technique it is the intensity of the Pb$M\alpha_{1,2}$ line which is measured instead of the usual Pb$L\alpha_1$, and when the concentration of bismuth in sodium carbonate is determined it is the Bi$M\alpha_{1,2}$ line and not the Bi$L\alpha_1$.

Extension of the Periodic Table

IN the course of an investigation concerning the behaviour of orbital objects around a nucleus, in which the properties of various simple theoretical models were studied to determine under what conditions the exchange of radiation and/or particles obeying the "inverse square law" could account for other interaction laws (not necessarily only at the nuclear or atomic level), the following series was found:

$$\frac{n_1}{1^2} + \frac{n_2}{2^2} + \frac{n_3}{3^2} + \ldots\ldots = 2k \quad (k = 1, 2, 3, \text{etc.})$$

It arose in more than one model, and is of little significance to the more ambitious main investigation. For example, the factor "2" in the right-hand side is to be expected whenever certain conditions of symmetry are postulated: and the left-hand side occurs at once when considering the "classical" potential energy of "n_r" electrons in the "r^{th}-th Bohr orbit[1]; and also in other models (for example, in which the radius of the "r"-th orbit is proportional to "r" and "inverse square law" attractions are summed)

Table 1

k	n_1	n_2	n_3	n_4	
1	2	—	—	—	
2	2	$1\,2.2^2$	—	—	
3	2	$2.2.2^3$	—	—	etc.
4	2	$2.2\,2^2$	$1\,2.3^3$	—	
5	2	$2.2\,2^2$	$2.2\,3^2$	—	
6	2	$2\,2.2^2$	$2.2.3^2$	$1\,2\,4^2$	
		etc			

From the infinite number of solutions of this equation, however, the regular pattern of solutions given in Table 1 is highly suggestive.

In the original investigation, the "n_1", "n_2", etc., referred to the number of orbital objects in successively remote orbits from the nucleus, and the regular pattern of solutions already given tallies precisely with the gross electron structures of the noble gases[2] as shown in Table 2.

Table 2

Gas	k	First period	Second period	Third period	Fourth period	Atomic No., that is $n_1+n_2+n_3+n_4+$ etc.
Helium	1	2	—	—	—	2
Neon	2	2	8	—	—	10
Argon	3	2	16	—	—	18
Krypton	4	2	16	18	—	36
Xenon	5	2	16	36	—	54
Radon	6	2	16	36	32	86

Continuing the pattern, one can predict the gross electron structures of all the noble gases yet to be discovered. For example, the next heavier one will have an electronic structure, corresponding to $k = 7$, of:

$$2 : 2.2.2^2 : 2.2.3^2 : 2.2.4^2,$$

that is $2 + 16 + 36 + 64$ = atomic number 118;

and the next after that, corresponding to $k = 8$, will be:

$$2 : 2.2.2^2 : 2.2.3^2 : 2.2.4^2 : 1.2.5^2,$$

that is $2 + 16 + 36 + 64 + 50$ = atomic number 168.

By noting how the intervals between the noble gases are occupied in the existing Periodic Table[3], a prediction can be made in some detail of the properties of all elements up to atomic number 118, the next noble gas; and a less specific, but more dramatic, prediction of the properties of even heavier elements can be made, as follows:

The regular pattern of solutions requires, of its very nature, that the intervals between successive noble gases go in pairs of equal numbers of elements; thus, from helium to neon is eight elements, as is the interval from neon to argon; from argon to krypton is eighteen elements, as is the interval from krypton to xenon; and so on.

With each successive pair of intervals, more and more elements have to be accommodated, so while there is a one-to-one correspondence between the elements in one interval and those in the "paired" interval, there has to be a drastic change when the next interval occurs. Thus, the eight elements from helium to neon match the eight elements from neon to argon; but the interval from argon to krypton copes with its larger number of elements by dispersing them fully into *A*- and *B*- sub-groups, and by introducing a transition group of three elements (iron, cobalt and nickel). The following interval from krypton to xenon matches this plan exactly, element-for-element. However, the next interval again, from xenon to radon, has so many elements that it must adopt an even more drastic plan, and in addition to using every available place in the Periodic Table it must lump together fifteen elements in a single place (the lanthanides, atomic numbers 57–71). On this scheme, the interval from radon to the next (undiscovered) noble gas should match the interval xenon to radon exactly, element for element, so that the fifteen elements from actinium (atomic number 89) to lawrencium (atomic number 103) should occupy only one place in the Periodic Table (refs. 4, 5 and 6 illustrate early discussion along these lines), and elements 108, 109 and 110 should be transition-type elements corresponding to osmium, iridium, and platinum, and so on.

There is reason to believe that extremely heavy atoms are most unstable[7,8] so the interval from atomic number 118 to 168 may never be reached. But if it is, because this starts another pair of intervals one can predict that a dramatic device to fit the elements into the interval will necessarily appear.

Fundamental Stretching Vibration in Liquid Water

WE have recently investigated the fundamental stretching vibration of liquid water in the infra-red region 4,000–2,000 cm^{-1} using the thin cell technique developed by Thompson[1]. The spectra, recorded under high-resolution conditions on a Perkin–Elmer 125 spectrometer, are shown in Fig. 1. It is apparent that the absorption in the 3,450 cm^{-1} region is complex and composed of three bands with frequencies of ~3,625 cm^{-1}, 3,410 cm^{-1} and 3,250 cm^{-1}. The band profile is almost identical to that observed in the Raman effect (see, for example, Schultz and Hornig[2]).

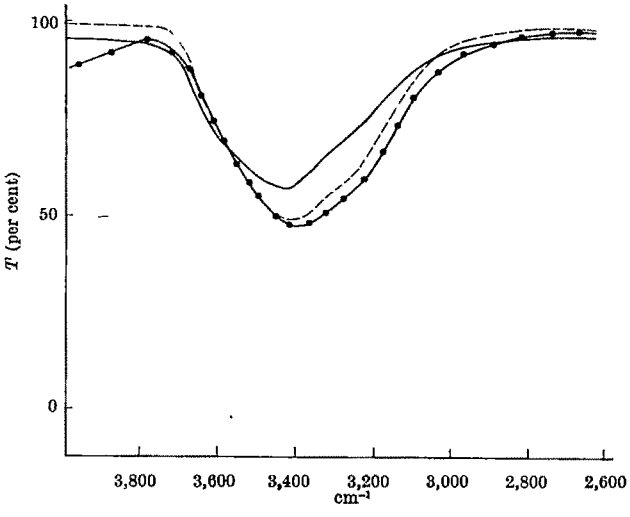

Fig. 1. Effect of temperature on the OH stretching absorption of water. – – – –, *c.* 35° C; ———, *c* 60° C; —●—, *c.* 5° C.

The most interesting observation, however, is the effect of temperature on the band system. As the sample is cooled from ambient temperature (~35° C when in the sample compartment of the spectrometer) to about 5° C, the intensity of the low-frequency band 3,250 cm^{-1} rises while that of the 3,625 cm^{-1} band falls. When the temperature is raised above ambient to about 60° C the 3,625 cm^{-1} band increases while the 3,250 cm^{-1} band decreases in intensity. Schultz and Hornig's[2] Raman spectra show exactly similar behaviour.

We now believe that the simplest explanation for these infra-red and Raman observations is in terms of three different types of water molecules with differing degrees of hydrogen bonding, as postulated by Buijs and Choppin[3] from their investigations of the combination band $\nu_1 + \nu_2 + \nu_3$ at ~8,300 cm^{-1}.

In the past we have advocated[4] a different explanation for the observed infra-red and Raman bands of liquid water using, like Schultz and Hornig, the idea of Fermi resonance to explain the Raman bands at 3,625 cm^{-1} and 3,250 cm^{-1} as a combination and overtone band respectively. At that time the available infra-red spectra indicated that our assignment was reasonable. In view of the infra-red data presented here, however, we believe that an explanation in terms of three types of water molecules is preferable to the earlier one which made use of the idea of Fermi resonance between bands separated by the order of 200 cm^{-1}. The assignment of the infra-red and Raman bands at 35° C is probably as given in Table 1.

The frequencies given in Table 1 for both infra-red and Raman results are taken directly from the recorded spectra. The differences between these three fundamental frequencies are consistent with the differences found by Buijs and Choppin[3] in the 8,300 cm^{-1} region in the infra-red.

Table 1

Raman	Infra-red	
3,620	3,625 cm^{-1}	Vibration of non-bonded water molecules
3,415	3,410 cm^{-1}	Vibration of water molecules with one proton involved in hydrogen bonding
3,250	3,250 cm^{-1}	Vibration of water molecules with both protons involved in hydrogen bonding

We are continuing our investigations on the temperature variation of the infra-red and Raman bands of liquid water and hope to enlarge on the use of spectroscopic data to define the properties of bulk water.

We thank Dr. C. Smart for advice and encouragement.

Photolytic Degradation of Textile Fibres in the Far Ultra-violet

Although it is generally recognized that the action of far ultra-violet radiation on textile fibres is photolytic in character, investigations of the influence of oxygen and water vapour on the complex reactions involved have been mainly confined to cotton cellulose. The temperature of the system and the parameter of degradation are other factors which profoundly influence the nature of the results[1]. In the experiments described here we have used as parameter the loss in tensile strength of the textile yarn which was exposed to the radiations from a low pressure mercury–vapour lamp emitting mainly at 2537 Å. The yarn was contained in the inner compartment of a brass cell fitted with a quartz window. The cell was maintained at a constant temperature by circulating a suitable heating (or cooling) medium through the outer compartment. During the experiment a stream of gas brought to the required temperature was passed through the cell. For the exposures (Fig. 1) in dry oxygen

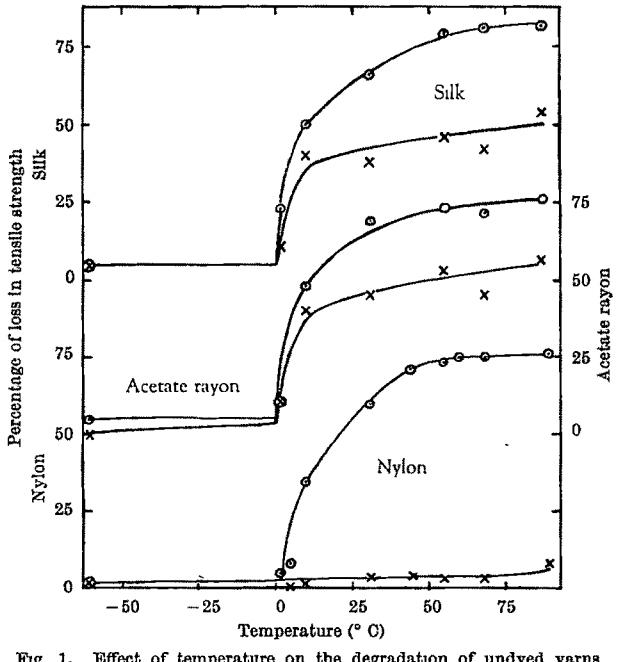

Fig. 1. Effect of temperature on the degradation of undyed yarns exposed to low pressure mercury-vapour lamp in dry oxygen (○) and dry nitrogen (×) for 20 h.

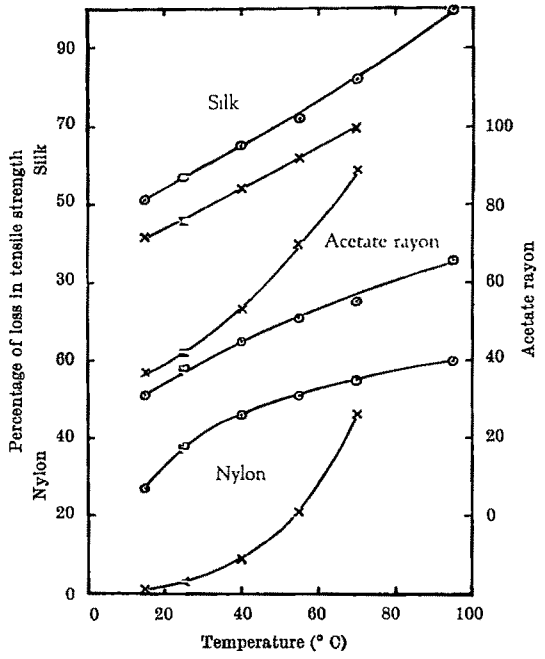

Fig. 2. Effect of temperature on the degradation of undyed yarns exposed to low pressure mercury-vapour lamp in air at 0 per cent relative humidity (○) and 100 per cent relative humidity (×) for 24 h.

and nitrogen involving temperatures down to −60° C the quartz face of the brass cell formed part of the wall of an airtight lamp chamber. At the bottom of the chamber was a tray of phosphorus pentoxide to absorb moisture and prevent the deposition of ice on the cold quartz plate. In addition a stream of dry nitrogen was passed continuously through the chamber. For the experiments (Fig. 2) with dry and moist air in which the lowest temperature was 15° C, this procedure was unnecessary and the cell was irradiated in a large well ventilated cupboard. Where dry gases were used they were dried with phosphorus pentoxide. In experiments performed in air at 100 per cent relative humidity, air was bubbled through a sintered glass filter immersed in distilled water which was maintained at the same temperature as the cell.

The effect of temperature on the degradation of some textile fibres exposed in dry oxygen and dry nitrogen to 2537 Å radiation is shown in Fig. 1. The fibres comprised scoured undyed yarns (free from delustrant or other additive) of nylon (hexamethylene diamine-adipic acid, Du Pont de Nemours, 4-fold, 45 den. 13 fil.), cellulose secondary acetate rayon (Courtaulds, 250 den. 48 fil.), and silk (degummed Japanese silk, 190 den.). With all three yarns the degradation in both gases is of negligible proportions at temperatures below about 0° C, but rises rapidly as the temperature is increased above this value. These results are in some contrast to those obtained with cellulose fibres. Results for undyed cotton yarn using fluidity in cuprammonium as the parameter of degradation have been reported[1] at temperatures down to 8° C. Further results at −60° C have shown that the change in fluidity (and also in reducing power) is of the same order as that at 5° C in the corresponding atmosphere. Moreover, with undyed cotton yarn (and also with scoured undyed viscose rayon) the loss in tensile strength in dry nitrogen and dry oxygen seems to be of the same order in the two gases and is only slightly affected by temperature over the range from −60° C to +90° C. As the temperature of the system falls to 0° C, it does not show the marked decrease in strength loss that is evident in Fig. 1 with silk, nylon and acetate rayon.

Nylon is particularly sensitive to the presence of oxygen in the irradiation system, and it would seem likely that in the absence of oxygen there is extensive recombination

of the free radicals formed on photolysis of the polyamide. Even in the presence of oxygen recombination would seem to be favoured at low temperatures. The reactions involved are undoubtedly complex as is shown by results which have been obtained with transparent films of nylon and other polymers[2], and may involve cross-linking of the polymer molecules[3].

The effect of temperature on the degradation of yarns of undyed silk, nylon and cellulose acetate rayon on irradiation in air at 0 and 100 per cent relative humidity is illustrated in Fig. 2. Except with acetate rayon the strength loss of the yarn is inhibited by water vapour. This effect is particularly evident with nylon, but as with acetate rayon, the strength loss increases substantially and at a much greater rate than in dry air, as the temperature is increased. The effect of water vapour on the degradation of cotton yarn by 2537 Å radiation has been shown[1] to depend on the parameter of degradation; the loss in strength being greater in the absence of water vapour, and the reverse being the case when the chain length of the cellulose (as measured by fluidity in cuprammonium) is considered. This evidence seems to suggest that in the presence of air and water vapour the polymeric free radicals formed on photolysis undergo secondary reactions involving not only gaseous oxygen but also water itself. It is possible that in certain circumstances hydrogen can be abstracted from a water molecule by the polymeric free radical. The resultant hydroxyl radicals would be expected to have a greater oxidative effect on cellulose than on polyamide fibres.

Formation of Cyclic Molecules by Macro-radical Reactions

MACRO-RADICALS formed by thermal degradation of polymers are known to participate in depolymerization[1] with subsequent detachment of a volatile compound. We have found another type of macro-radical reaction, namely, the formation of cyclic molecules.

A radical $\sim OCH_2—OCH_2—O\dot{C}H_2$ is formed by thermal degradation of polyformaldehyde. As a result of chain conformation by addition of a free-valency carbon atom to oxygen or to another carbon atom this radical may form cyclic atoms of trioxane:

or of dioxalane:

These were identified by means of chromatography and mass-spectrometry. Sometimes cycles with many links are also formed; this was demonstrated by mass-spectrometry.

Similar macro-radical reactions were observed during an investigation of the thermal degradation of polyvinylchloride. Here hydrochloric acid is the primary reaction product. Its detachment results in the formation of a macro-radical with a system of conjugated bonds:

$$\sim CH = CH - CH = CH - CH - \dot{C}H$$

In closing the cycle this radical is capable of detaching a benzene molecule. Benzene formed as a secondary product was identified by chromatography or mass-spectrometry.

So far as we know, no such cyclization of radicals in the degradation of polymers has previously been reported, though similar reactions of light radicals are known[2].

BIOCHEMISTRY

Effect of Temperature on s-Ribonucleic Acid Aggregation induced by Magnesium Ions

RECENTLY, the aggregation of *s*RNA from *Escherichia coli* has been reported[1]. At neutral *p*H and at 25° C the aggregation process is dependent on nucleic acid and magnesium ion concentration. In 0·02 M magnesium, the aggregates dissociate into monomer units at low nucleic acid concentrations. This report shows that a modest increase in temperature (from 25° C to 45° C) partially dissociates the aggregates and that the decrease in molecular weight is reflected in the viscosity thermal profile.

E. coli *s*RNA was obtained from General Biochemicals, Chagrin Falls, Ohio, and freed of protein by repeated mechanical shaking with phenol. The aqueous supernatant was then chilled and the *s*RNA precipitated with two volumes of an ethanol–potassium chloride (0·3 M) solution. This was repeated twice. The final precipitate was dissolved in 0·01 M ethylenediamine tetraacetic acid (EDTA) and dialysed overnight against 0·01 M EDTA at 4° C. The solution was then treated twice with bentonite—50 mg/25 ml. of solution[2]. EDTA was then removed by dialysis against frequent changes of doubly distilled water at 4° over a period of 72 h. The aqueous *s*RNA was finally lyophilized.

The calibration, thermal control, use and calculation procedures with the Price–Phoenix light scattering photometer have already been described[1]. The instrument was modified in one respect; a narrow slit nosepiece was mounted in front of the photometer and the instrument refocused by a reflectance method. Viscosity measurements were made with a Ubbelohde viscometer with a solvent flow time of about 90 sec (25° C) or with a conventional viscometer with a 0·8 mm bore having a flow time of about 300 sec (25° C). Temperature regulation in viscometry was achieved as previously described[1]. For either viscometry or light scattering measurements, dust was removed by 'Millipore' filtration. *s*RNA concentration was estimated spectrophotometrically[3].

A low ionic strength medium used in these and previous investigations[1] was chosen on the basis of the observations of Lipsett *et al.*[4]. These investigations clearly show a competition between moderate concentrations of neutral salt and magnesium ions for binding sites on polyribonucleotides and suggest that an investigation of the effects of magnesium ions on nucleic acids should be made in a low ionic strength medium.

Fig. 1 shows the effect of increasing temperature on the molecular weight of *s*RNA. In neutral salt, the apparent

molecular weight (about 25,000) is only slightly decreased as the temperature is raised to 45° C, and essentially quantitative reversibility is obtained when the solution temperature is brought back to 25° C. In solutions which are 0·02 molar in Mg^{2+} and 0·01 molar in potassium acetate, the molecular weight of the aggregated form of *s*RNA at 25° C is roughly equal to that of a dimer. Heating to 45° C results in a drop to about 37,000. The process is about 95 per cent reversible, as is indicated by the checked circles. Heating to temperatures much above 45° C for longer periods of time in the presence of magnesium results in extensive aggregation[1].

Fig. 2 shows the intrinsic viscosity in the presence of magnesium ions at 25°, 35° and 45° C. At 25° C, the variation in η_{sp}/C with concentration clearly reflects the dissociation process reported earlier[1]. At 35° and 45° C the dependence of η_{sp}/C on concentration is less than that at 25° C. This is probably a consequence of the decrease in degree of aggregation at each of these temperatures (Fig. 1) although possible conformational changes cannot be ruled out. Linear extrapolation of the 25° C data above 3 mg/ml. leads to a value of $0{\cdot}074_5$ dl./g for the aggregate form, in good agreement with the value of 0·076 dl./g reported earlier[1]. In view of the scatter of the data below 3 mg/ml. at 25°, 35°, and 45° C, apparent intercepts at zero concentration were averaged giving 0·041 ± 10 per cent dl./g for the monomeric form of *s*RNA in magnesium ions.

These results show that the aggregation of *s*RNA induced by magnesium ions is, within a limited temperature range, thermolabile. In this respect it resembles the low temperature aggregation reported by Henley *et al.*[5]. The nature of the aggregation is unknown. Whether it results from magnesium ion phosphate links or base–base interaction or both is at present conjectural.

In solutions which are 0·3 molar in potassium chloride and 0·01 M molar in potassium acetate, the intrinsic viscosity at 25° C of *E. coli* *s*RNA monomer is 0·059 dl./g (ref. 6). Clearly, in a low ionic strength magnesium ion containing solvent the effective hydrodynamic volume of

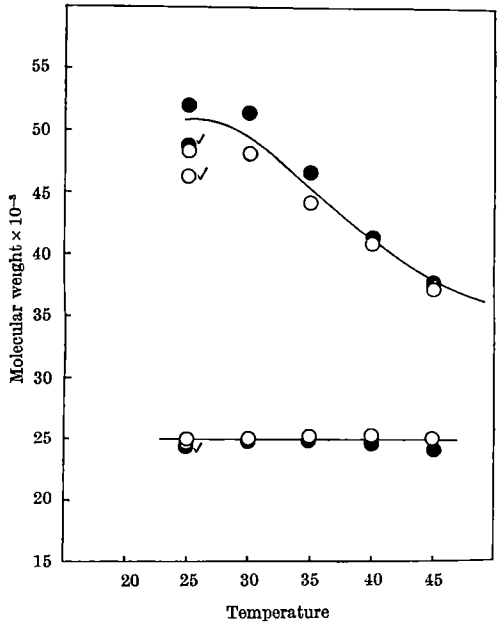

Fig. 1. The effect of temperature on the molecular weight of *s*RNA. ○, *s*RNA XI, ●, *s*RNA XII. Solvent systems: upper curve, 0·02 molar in magnesium acetate and 0·01 molar in potassium acetate, *p*H 7·0. *s*RNA XI, 4·25 mg/ml.; *s*RNA XII, 3·2 mg/ml. Lower curve, 0·3 molar in potassium chloride and 0·01 molar in potassium acetate. *s*RNA XI, 3·8 mg/ml.; *s*RNA XII, 2·95 mg/ml. Reversal from 45° to 25° C indicated by checked circles. Light scattering artefacts arising from thermal effects on the cell housing block and cell were corrected by measuring the turbidity of a 1 per cent solution of bovine serum albumin as a function of temperature. All solutions were kept 5 min at temperature before results were recorded.

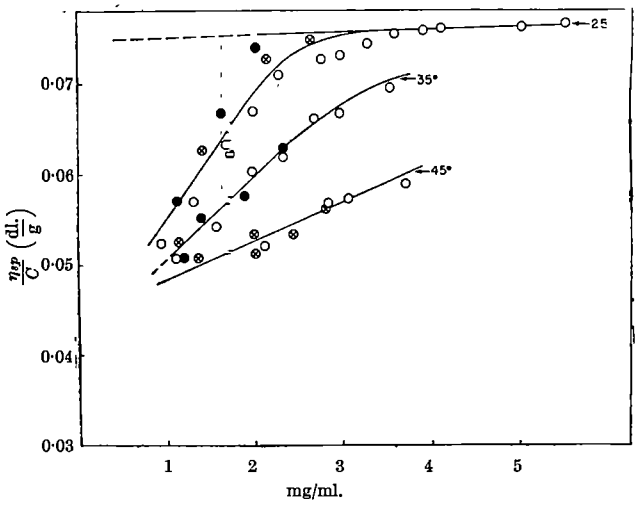

Fig. 2. Determination of the intrinsic viscosity of *s*RNA in 0·01 M potassium acetate, 0·02 M magnesium acetate, *p*H 7·0, at 25°, 35°, and 45° C. ○, *s*RNA IX; ⊗ *s*RNA XI; ●, *s*RNA XII. About 97 per cent reversal was obtained when any of the three preparations used was cooled from 45° to 25° C.

*s*RNA is less than that in moderate concentrations of neutral salt. The imprecision of the viscosity data prevents any meaningful estimation being made of the size of the equivalent ellipsoid of revolution.

If this reduction in effective hydrodynamic volume reflects only a difference in shape of *s*RNA in the two solvent systems, then it is conceivable that the effect of magnesium ions of raising the T_m from 57°–58° C in solutions which are 0·3 molar in potassium chloride and 0·01 molar in potassium acetate (*p*H 7·0)[6] to 77°–78° C in solutions which are 0·02 molar in Mg^{2+} and 0·01 molar in potassium acetate (*p*H 7·0)[1] simply results from a relief of electrostatic stress which compacts the molecule and strengthens secondary forces. Alternatively, a more complex conformational transition cannot be excluded. Finally, it should be noted that the hypothesis outlined here may be restricted to the solvent system described.

Optical Rotatory Dispersion of Phosvitin

Previous investigations of phosvitin in solution have shown that the specific optical rotation, [α], in the visible and near ultra-violet regions is highly dependent on the *p*H and to a certain extent on the solvent composition. Furthermore, it has been reported that the rotatory dispersion constant of this protein varies with *p*H, λ_c = 225 mμ at *p*H 4·7 and 207 mμ at *p*H 10.75 (refs. 1 and 2).

During a characterization of the chemical properties of phosvitin, prepared according to the procedure of Joubert and Cook[3], the optical rotatory dispersion of this protein was recorded over the wavelength range of 600–190 mμ using a Cary 60 recording spectropolarimeter. In the spectral regions removed from absorption bands, the rotatory dispersions fit the one-term Drude equation.

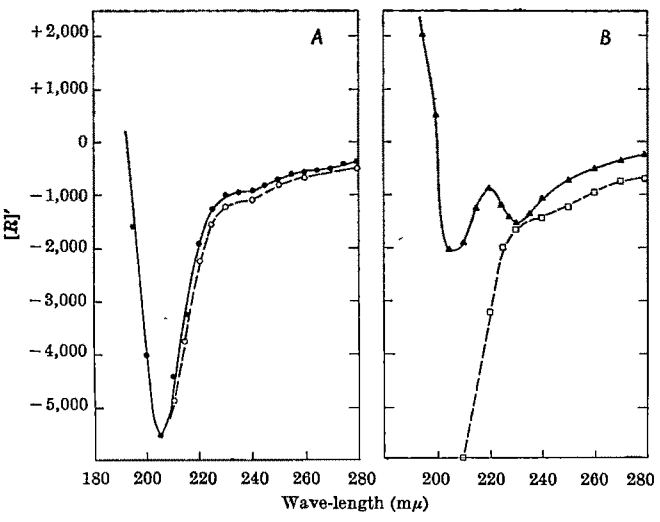

Fig. 1. Far ultra-violet rotatory dispersion of phosvitin. *A*, ●——●, In 0·032 M sodium monohydrogen phosphate–0·004 M sodium dihydrogen phosphate, *p*H 7·7 and ionic strength 0·1; ○— — ○, in 8·0 M urea-phosphate. Protein concentration: 0·01 per cent. *B*, ▲——▲, In distilled water; □— —□, in 0·1 N sodium hydroxide. Protein concentration: 0·04 per cent.

In a sodium phosphate buffer of *p*H 7·7 and ionic strength of 0·1, λ_c = 220 mμ, which agrees well with that found by Jirgensons[1,2]. If the protein is dissolved in 8·0 M urea-phosphate of apparent *p*H 7·7, λ_c = 218 mμ, thus duplicating the behaviour of other proteins with a low dispersion constant where urea has no effect on the specific optical rotation[4]. An intrinsic Cotton effect occurs in the far ultra-violet optical rotatory dispersion of phosvitin. As Fig. 1*A* illustrates, this Cotton effect has an inflexion point at 193 mμ and a minimum at 205 mμ. Such a negative Cotton effect with a trough at 205 mμ has thus far only been reported for collagen[5]. As also indicated in Fig. 1*A*, the residue rotation $[R]'$ is not altered if the protein is transferred from aqueous solution to 8·0 M urea-phosphate. The far ultra-violet dispersion of phosvitin dissolved in distilled water, a solution with resulting *p*H of 3·3, revealed two intrinsic negative Cotton effects with minima at 205 and 232 mμ respectively (Fig. 1*B*). Finally, we note some observations on the Cotton effect of a phosvitin solution on 0·1 N sodium hydroxide at *p*H 12·2. Although it was not possible to record the optical rotation in this solvent below 208 mμ, it is nevertheless apparent from Fig. 1*B* that the residue rotation in 0·1 N sodium hydroxide is larger in magnitude than that in phosphate buffer of *p*H 7·7.

As we have reported elsewhere[6], 56 per cent of the amino-acids of phosvitin are phosphoserine and phosphothreonine, 12 per cent dicarboxylic, 17 per cent basic, and only 15 per cent non-polar amino-acids. Thus the predominance, in this protein, of acidic constituents must considerably influence its conformational pattern. The dependence, therefore, of the macromolecular conformation on *p*H or on solvent composition is not surprising. At *p*H 3·0, for example, not all acidic groups are dissociated, whereas in the *p*H range of 7·0–8·0 some of the acidic groups may be neutralized by the proximity of the basic amino-acids. Furthermore, the possibility of O→N migration of the phosphoryl groups at neutrality[7,8] or β-elimination and formation of dehydroalanine at extreme alkalinity[9] are all factors that have to be considered in an attempt to understand the conformational pattern of this protein. Whatever interpretation of the optical rotatory dispersion curves of phosvitin will finally be established, we feel it is essential at this point to warn against any overemphasis of the rotation measurements in terms of a known conformational pattern unless supplemented by other chemical and physico-chemical methods or by work on known model compounds.

The Cary 60 spectropolarimeter was kindly made available to us by Dr. William F. Harrington, whom we thank for many helpful suggestions. Some of the experiments were carried out at the Marine Biological Laboratory, Woods Hole, Massachusetts.

This work was supported in part by a grant from the National Science Foundation.

Inhibition and Possible Feedback by 6-Methylsalicylic Acid

WHEN commenting generally on secondary metabolic phenomena and on the particular example of the synthesis of 6-methylsalicylic acid (6-MS) in *Penicillium urticae* Bainier (≡*P. patulum* Bainier, etc.), we referred[1] to unpublished evidence suggesting that 6-MS could exert feedback inhibition on its own synthesis. Recently, Arihood and Light have described[2] investigations of this problem, and have reported that the addition of 6-MS, or of certain related compounds, inhibits the incorporation into 6-MS of carbon-14 from exogenous 1-^{14}C-acetate in intact mycelium. Our own work, however, revealed unsuspected complexities in this type of experiment. These have been summarized elsewhere[3], but the publication of Arihood and Light prompts us to record some of our evidence in more detail. The basic experimental techniques and the general dynamics of 6-MS synthesis have already been described[4].

At first we studied the gross levels of 6-MS in the medium of *P. urticae* cultures to which had been added, at various stages, 6-MS in the concentration range $2 \sim 6 \times 10^{-4}$ M (that is, about a tenth of the concentrations used by Arihood and Light). Normally, any mycelial accumulations of 6-MS can be neglected, but this is not so when extra 6-MS is added suddenly. This can be shown by spectrophotometric assay of 6-MS in the aqueous medium; the time-scale of events varies somewhat with the age, phase, and history of the mycelium, but the same qualitative behaviour is consistently observed. For example, on taking a suspension of 13 mg/ml. (wet weight) mycelium in fresh medium and adding 80 μg/ml. of 6-MS, there is a rapid removal of about 25 μg/ml. from the medium, in the first 30–60 min, followed by a slower reappearance over the next 2 h. This occurs even with trophophase mycelium, which has not yet commenced 6-MS synthesis[4]. In similar experiments, using 1-^{14}C-6-MS and recovering the 6-MS by co-crystallization with carrier, the specific activity of 6-MS shows little or no change. Thus, after the initial uptake of 6-MS, its subsequent reappearance does not arise from synthesis of 6-MS but from expulsion of the exogenous material, undiluted, possibly as a result of changes in the internal *p*H of the mycelium. Only in late idiophase mycelium which is actively converting 6-MS into patulin[4] is this picture materially altered.

With this complication added to the fact that even in control cultures the endogenous 6-MS is a reaction inter-

mediate present in fluctuating amounts[4] it was clear that measurements of gross levels of 6-MS following 6-MS addition would not give any information concerning the actual synthesis of 6-MS. Accordingly, we turned to the type of experiment which Arihood and Light have now described[2], in which early idiophase mycelium of *P. urticae* was incubated with added 6-MS and 1-^{14}C-acetate, and the fate of the carbon-14 observed. We found that, even at concentrations of $4 \sim 6 \times 10^{-4}$ M, 6-MS almost completely inhibits the incorporation of exogenous 1-^{14}C-acetate into 6-MS, and this is immediate. The isomeric analogue 3-methylsalicylate (3-MS) is equally effective. Thus far our observations coincide with those of Arihood and Light. We found, however, that the inhibitory effects are actually more widespread. At the same levels of 6-MS and 3-MS there is, for example, a comparably drastic inhibition of the incorporation of exogenous carbon-14 into lipids, mannitol, mycelial insolubles, and respired carbon dioxide, which is observed whether the carbon-14 is supplied as acetate or as glucose. Moreover, there is a comparable inhibition of the total carbon dioxide evolved and of dry weight increase and lipid synthesis during the incubation. In brief, these substances are acting as general inhibitors of metabolism. We are uncertain as to whether or not this effect is related to the effects of salicylates on oxidative phosphorylation.

These effects adequately explain the data of Arihood and Light[2], using rather higher concentrations, and also certain anomalous results which have been described, such as the observations of Tanenbaum and Bassett[5] on the rate of patulin synthesis by *P. urticae* in the presence of ^{14}C-6-MS, and of Packter[6] on the effects of 6-MS on the synthesis of fumigatin in *Aspergillus fumigatus* (allegedly from 6-MS but compare with ref. 7). It is also possible, however, to observe a more specific action of 6-MS on *P. urticae* by operating at somewhat lower levels. At $5 \sim 10 \times 10^{-5}$ M, for example at 7 μg/ml., 6-MS still inhibits the synthesis of 6-MS, as revealed by the recovery of undiluted material after incubations of idiophase mycelium with 1-^{14}C-6-MS for 0·5–2 h, yet at this concentration the more general inhibitory effects are comparatively slight. The analogue 3-MS does not seem to show this selective effect. It is for this reason that we adduced the 6-MS synthesis system of *P. urticae* as a possible example of the operation of product inhibition, or a similar feedback mechanism, in secondary biosynthesis, though a conclusive test must await the description of a reliable procedure for the study of polyketide synthetases in cell-free preparations.

Effect of Orchidectomy and Ovariectomy on Survival against Lethal Infections in Mice

The reticulo-endothelial system plays a predominant part in the defence of the body against infection. We have previously shown that stimulation of the reticulo-endothelial system leads to raised body defence (indicated by increased phagocytic activity, accelerated antibody production, raised serum gamma globulin and increased protection of experimental animals against virulent infections), and that the strongest reticulo-endothelial stimulants are the oestrogens[1,2]. We have also shown that the action of oestrogen on the reticulo-endothelial system is independent of its action on the reproductive tract, although these two biological activities are contained in the same molecule[3]. We have also demonstrated that cyclical variations in reticulo-endothelial activity occur during the oestrous cycle and during pregnancy in the rat and the mouse[1]. These findings suggest that when protection against infection is required, general and local body defence is increased by raised blood oestrogen levels. We also found that reticulo-endothelial activity falls after ovariectomy in the mouse[4]. These results suggest that oestrogen, especially 17β-oestradiol, is the principal natural stimulant of body defence in both the male and the female—the latter having raised oestrogen levels when protection against infection is normally most needed.

The purpose of this communication is to report the effects of ovariectomy and orchidectomy on resistance to lethal doses of virulent organisms, and to demonstrate the protective effect of oestrogen administration in intact and gonadectomized animals.

Forty male and forty female white mice (*T.O.* Swiss strain) of 20–25 g body-weight were used in the experiment. The orchidectomized and ovariectomized animals were spayed 4 weeks before the experiment started. The mice were divided into eight groups, each containing ten animals, as shown in Table 1. In the oestrogen treated groups, each dose of diethylstilboestrol (0·1 mg) was administered orally by stomach tube in 0·1 ml. of sterile distilled water[5] once daily for 3 days. On the day following the last dose of diethylstilboestrol, all the animals received a single intraperitoneal injection of 0·2 ml. of 1/10 dilution of an 18 h broth culture of *Pneumococcus* Type 1 (about 10,000–100,000 lethal doses). The number of animals surviving was noted at 2-hourly intervals. The mean survival times were calculated according to one of the methods used by Burroughs Wellcome Laboratories[6]. The survival time for each animal was recorded and converted into the reciprocal; the reciprocals were then handled as normal variates and averaged within groups in the ordinary way.

Table 1. Mean Survival Times of *T.O.* Swiss Mice infected with *Pneumococcus* Type 1 following Orchidectomy and Ovariectomy and after Treatment with Diethylstilboestrol

Group	Daily dose of diethylstilboestrol for 3 days before infection (mg)	Dose of infection	No. of animals in group	Mean survival time ± S.E. (h)
Intact males	—	0·2 ml. of 1/10 dilution of 18-h broth culture of *Pneumococcus* Type 1 (about 10,000–100,000 lethal doses) intraperitoneally	10	15·1 ± 0·7
Orchidectomized males	—		10	11·8 ± 0·6
Intact males + diethylstilboestrol	0·1		10	24·9 ± 1·4
Orchidectomized males + diethylstilboestrol	0·1		10	23·2 ± 1·6
Intact females	—		10	15·3 ± 0·8
Ovariectomized females	—		10	11·2 ± 0·9
Intact females + diethylstilboestrol	0·1		10	27·3 ± 1·3
Ovariectomized females + diethylstilboestrol	0·1		10	23·8 ± 1·2

Broth: Oxo Nutrient No. 2 with 15 per cent horse serum.
Mean survival times were calculated according to the method of reciproca survival with observations every 2 h.

The results are shown in Table 1. It can be seen that there was no difference in the mean survival times of the untreated intact males and females. It can also be seen that orchidectomy and ovariectomy significantly reduced the survival time to about the same level. The administration of diethylstilboestrol produced a marked increase in survival time in both the intact and gonadectomized

animals, there being no significant differences between the various groups receiving oestrogen.

The observations recorded in this experiment clearly show that removal of the gonads significantly reduces survival against large doses of highly virulent infection in both sexes. In the human male it is known that considerable quantities of oestrogen are produced by the adrenal cortex and testes, and that, following orchidectomy, there is a marked fall in the urinary excretion of oestrogen[7]. In the human female, increased production of oestrogen by the adrenal cortex compensates, to some extent, for the removal of the ovarian sources of these hormones[8], but the increase is not sufficient to restore body defence to pre-operative levels[4]. Furthermore, it has been shown that, following ovariectomy in women of premenopausal age, there is a significant increase in the susceptibility to certain diseases[9]. Thus, it appears that gonadal oestrogen plays an important part in maintaining body defence in both sexes.

We have previously demonstrated that diethylstilboestrol prolongs survival against a wide variety of virulent Gram-positive and Gram-negative organisms in intact male mice[1]. The present results show that diethylstilboestrol is equally effective in prolonging survival in both intact and gonadectomized animals of both sexes.

The present results provide additional evidence in support of our earlier postulate that oestrogen is the principal natural stimulant of body defence in both the male and the female; and, further, that oestrogen treatment would seem to be of clinical value in the treatment of acute bacterial infections.

BIOLOGY

Stimulation of Spawning in *Xenopus laevis* by Fowl Manure

SAVAGE[1] found that pondweeds in the presence of light stimulate spawning in *Xenopus laevis* in the laboratory. This finding prompts me to report my own experience with this amphibian under more natural conditions in the Transvaal.

At the Provincial Fisheries Institute, Lydenburg, fishponds that have been dry for the winter are filled with water and fertilized with fowl manure in spring for the breeding of fish. Within 2 or 3 days after fertilization such ponds usually contain large numbers of *Xenopus*, which immediately start spawning, so that by the time plankton has developed the pond is teeming with larvae.

On such a station, these frogs are usually spread over numerous ponds, but fertilized water is so attractive to them that they can be collected simply by fertilizing a pond and netting the frogs from it after a few days. They come from adjacent ponds overnight even when these are not receiving seepage from the fertilized pond. It is suspected that they are able to detect fertilized water by scent when coming up for air or while travelling overland at night.

The fact that they are attracted by fertilized water and spawn before an algal bloom develops suggests that the primary stimulus for spawning under these conditions could be the fertilizer rather than an algal metabolite.

Coat Structure in Soay Sheep

EARLIER work on the coat of the Soay[1,2] was carried out with "mainland" Soays which stem from stock removed from St. Kilda some 50 years ago. Apparently, all these animals have a woolly, chocolate coloured coat. The designation of St. Kilda as a National Nature Reserve has enabled an investigation to be made of the sheep remaining on the islands by a team organized by the Nature Conservancy[3]. Many of the sheep have a hairy coat, and only 75 per cent are dark brown in colour; the remainder are light brown. The coat structure of these primitive domestic sheep throws light on fleece evolution. This study reveals a lack of heterotype hairs, and a higher secondary/primary follicle ratio (S/P ratio) in the hairy than in the woolly type.

Mid-side coat and skin-snip samples were taken in August 1963 from twenty-four animals removed from St. Kilda that year, and in May 1964 from twenty animals on Hirta, St. Kilda.

Despite gradation in the type of coat, it was possible to divide the samples into hairy and woolly types by eye. Of the dark animals 63 per cent had a hairy coat, compared with 60 per cent of the light animals. The hairy type was characterized by straight hairy fibres projecting beyond the rest of the coat, whereas the woolly type had more definite staples with a curly tip. Most rams had a hairy coat. The hairy fibres are apparently kemps, and although these are finer than those of the wild sheep[4], the coat often resembles that of the Mouflon. No evidence was found for heterotype hairs, that is, hairs that are kemp-like in summer but narrow and non-medullated in winter. Hairy sheep had a longer coat than woolly sheep, and there was a tendency for the dark animals to have a longer coat than the light ones, so that the coat lengths in August (grown since the spring moult) ranged from a mean of 22·5 mm in the light woolly sheep to a mean of 35 mm in the dark hairy ones. This trend was not obvious in the animals with a year's growth of wool (sampled in May); this may have been the result of equalization of hair lengths through wear at the tips, and of shedding of the longest hairs. In only one of these animals did the coat length (80 mm) exceed 50 mm. The maximum length found in mainland Soays was 50–60 mm.

The mean fibre diameter was about 25μ in the woolly sheep, and about 30μ in hairy ones, ranging up to a mean of 35μ in dark, hairy animals. This compares with a mean in some mainland Soays of 23·5μ. There was a "skewed-to-fine" distribution, and the overall diameter range in woolly animals was 12–48μ in August, although some animals had a few hairy fibres up to about 70μ in diameter. In May the range was similar with little apparent reduction in the diameter of either the wool or the hairy fibres. The diameter range in the hairy animals was 12–144μ in August and 10–106μ in May. This contrasts with some spring measurements in the Mouflon

of the outer kemp: 40–190μ (narrowing to shed), mean 144μ; and under wool: 6–18μ, mean 12μ.

Examination of skin sections showed the primary fibres in August to be very variable. At one extreme were coarse fibres with a wide, latticed medulla like that of kemps in cross-section. Some less coarse fibres had either the same extremely wide latticed medulla, or a narrower latticed medulla comparable with that of heterotypes. At the other extreme some fibres were of medium diameter, and had either a non-latticed medulla or no medulla. The central primaries tended to have coarser fibres than the laterals, but not fibres of a different type. There was more variation in fibre type between animals than between different fibres of the same animal. Most coat variation seemed to be the result of differences in the type of primary fibres. There was little apparent variation in the diameter of the secondary fibres, and few exhibited any medullation. A greater density of pigmentation was frequently seen on one side of the secondary fibres than the other[5].

The mean proportion of primary fibres with a latticed medulla was 34 per cent in the dark, hairy animals and 38 per cent in the light, hairy ones. But of these 91 per cent were of the wider type in dark animals, compared with only 67 per cent in the light animals. These figures accord with the tendency for the dark animals to have a coarser coat. The dark and light woolly sheep had a similar proportion (27 per cent and 28 per cent) with a latticed medulla—32 per cent and 39 per cent respectively, having the wider type. The proportion of non-latticed medullation ranged from 10 per cent to 15 per cent in the different groups. The animals sampled at the end of May were about to shed their fleece; by this time most fibres had ceased to have any medullation and many had a brush end. This is in keeping with a complete moult, and supports the identification of the hairy fibres as kemps.

About 75 per cent of both the primary and secondary fibres were pigmented in August, but whereas 63 per cent of the primaries and 49 per cent of the secondaries had dense pigmentation in the dark group, the figures were only 13 per cent and 10 per cent in the light group. The difference in colour between light and dark animals is, therefore, mainly the result of differences in the density of pigmentation, and less the result of differences in the number of pigmented fibres. Pigmentation was not so great in the skin of animals sampled in May, in keeping with preparation to shed the fleece.

Preliminary results indicate that at birth less than 10 per cent of the secondary follicles are growing fibres. Side[6] found that in the Mouflon no secondary fibres were above the skin surface at birth. In contrast, a 135 day Romney foetus had about 80 per cent of the secondary follicles with fibres[7], while at 1 day of age the Herdwick had about 60 per cent[8] and the Suffolk 85 per cent[9]. In the two week old Soay, the proportion of mature secondaries had increased to a mean of 50 per cent and of these as many as 59 per cent had outgrowths like those observed by Ryder[2]. Follicle branching therefore seems to be important in the development of later secondaries in the Soay.

The mean S/P follicle ratio for all sheep sampled on St. Kilda was 3·86/1, compared with 3·59/1 in mainland Soays. The mean S/P ratio of woolly animals on St. Kilda was 3·59/1 (range 3·2/1 to 3·7/1) and that of the hairy sheep was 3·95/1 (range 3·2/1 to 4·7/1), this difference being significant at the 2 per cent level.

This paradox whereby the hairy animals have a higher instead of a lower S/P ratio probably lies in the primitive nature of the Soay coat. Thus the hairy type is probably closer than the woolly type to the Mouflon, which has a relatively high S/P ratio approaching 5/1 (ref. 4). This is higher than in many domestic breeds, for example Scottish blackface, 3–4/1. Animals with a similar S/P ratio can have markedly different coat types resulting from differences in the type of primary fibre (compare the Mouflon and Down fleece, both with an S/P of 5/1). Thus the S/P ratio is not necessarily associated with fineness, and may only become important when the primary fibres are not coarse, and when it exceeds about 5/1. Fineness in the Merino, however, is associated with high follicle density, and so in this breed fineness is not directly associated with a high S/P ratio, which here appears merely to reflect the high follicle density.

The lack of heterotype hairs, and the "skewed-to-fine" distribution of fibre diameter, supports the identification of the Soay with the generalized medium wool type[10], and the hairy type as being a hairy medium wool. The affinity with the Mouflon indicated by this investigation suggests that a gradual evolutionary replacement of kemps with heterotypes did not occur. The heterotype seems to be a specialized and highly evolved fibre type, the origin of which is probably associated with the change from moulting to continuous growth.

In order to investigate the possibility that heterotypes could be produced as a result of a cross, some Merino ewes (fine wool only) were mated with a Mouflon ram (kemp and fine wool). The progeny are now a year old; all their secondary follicles are growing wool, and all their primary follicles are apparently growing kemp. Thus no evidence for heterotypes has yet been found.

I thank the Nature Conservancy for facilities to study these animals. I also thank Mr. H. B. Scott and Miss M. T. Butler for technical assistance.

Cytokinins in Ribonucleic Acids

COMPOUNDS which, like kinetin (6-furfurylaminopurine), induce cell division in certain excised plant tissues have been termed cytokinins[1]. A number of synthetic substances (6-substituted purines, 1-substituted adenines and urea derivatives) show this characteristic. The most active natural cytokinin so far discovered is also a substituted purine, termed zeatin [trans-6-(4-hydroxy 3-methyl but 2-enyl) aminopurine]. This was isolated from *Zea mays* seeds[2]. Other natural cytokinins, as yet unidentified, occur in many other plant tissues, but there have been no reports of the occurrence of cytokinins as natural constituents of animal tissues. This communication, however, provides evidence that compounds with cytokinin activity are natural constituents of animal soluble RNA.

Mixtures of highly purified RNA and DNA were prepared (by methods described previously[3]) from rat and sheep liver, and from exponential phase tobacco cells (*Nicotiana tabacum* var. 'Wisconsin 38') grown in cell suspension culture. RNA was hydrolysed in 1 N potassium hydroxide at 25° C for 24 h to give a mixture of 2′- and 3′-ribonucleotides. The hydrolysate was neutralized by passing it through a column of 'Zeocarb 225' (ammonium) cation exchange resin (10 cm × 0·5 cm) and evaporating it to dryness. Ribonucleotides were extracted from this dried eluate with 70 per cent ethanol, *p*H 4. The insoluble

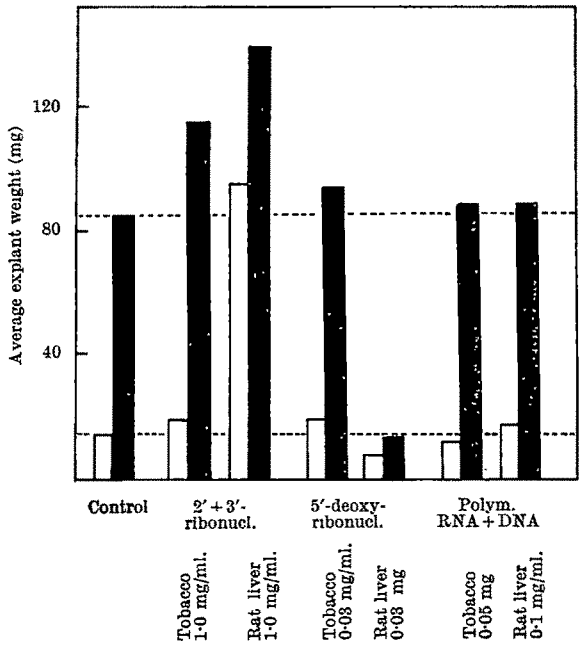

Fig. 1. Average weight of carrot explants after growth in the presence and absence of tobacco cell and rat liver nucleic acids and their hydrolysis products. Kinetin was added to some treatment (0·2 mg/l.). The following fractions were assayed at the levels indicated/ml. culture fluid: 2′- and 3′-ribonucleotides (alkaline hydrolysis); 5′-deoxyribonucleotides (enzyme hydrolysis); unhydrolysed (polymeric) nucleic acids (RNA+DNA); control (indole-3-acetic acid alone). □, Fractions plus indole-3-acetic acid alone; ■, fractions plus indole-3-acetic acid and kinetin.

DNA which remained was digested to 5′-deoxyribonucleotides by treatment with DNase I (deoxyribonucleate oligonucleotido-hydrolase, E.C.3.1.4.5) followed by treatment with purified snake venom phosphodiesterase (orthophosphoric diester phosphohydrolase E.C.3.1.4.1)[4]. RNA and DNA were also hydrolysed to the mixed 5′-ribo- and 5′-deoxyribonucleosides using crude snake venom[5]. Protein was removed from the enzyme hydrolysates by 70 per cent ethanol extraction as before.

To assay for cytokinin activity, nucleic acids and hydrolysates were filter-sterilized, and their effect on the growth of phloem explants[6] was determined. All culture media used contained the growth factors indole-3-acetic acid (2 mg/l.) and myo-inositol (50 mg/l.). All extracts were assayed both in the presence and in the absence of an added synthetic cytokinin (kinetin, 0·2 mg/l.) in order to check for the possible presence of inhibitory compounds or synergistic effects.

Alkaline hydrolysates of sheep and rat liver RNA showed considerable cytokinin activity, while tobacco RNA hydrolysates were inactive. All deoxyribonucleotide preparations were inactive or were inhibitory (Figs. 1 and 2).

Enzyme hydrolysates of sheep liver RNA showed a similar cytokinin activity to that of alkaline hydrolysates of this material (Fig. 2). Thus the activity in alkaline hydrolysates of RNA is not likely to be an artefact caused by the strongly basic conditions of hydrolysis. On the other hand, a mixture of pure ribonucleotides (Pabst Laboratories) was inactive, showing that the cytokinin activity was not due to the four major ribonucleotides found in RNA.

The possibility was considered that the compounds with cytokinin activity may be confined to RNA from one particular part of the cell. Rat liver was therefore homogenized (0·25 M sucrose, 0·025 M potassium chloride, 0·005 M magnesium chloride, 0·05 M *iris*-hydrochloric acid, *p*H 7·8) using a tapered glass homogenizer (Kontes Glass Co.); and the sub-cellular particles were isolated from the resulting homogenate by differential centrifugation. RNA was prepared from each fraction and hydrolysed to 2′- and 3′-ribonucleotides as before. Each fraction was assayed for cytokinin activity. The nuclear, mitochondrial and ribosomal RNA hydrolysates (0·35 OD_{260}/ml. culture fluid) caused moderate growth increments, but RNA from the cytoplasmic fraction (105,000*g* supernatant, principally *s*RNA), though at a lesser concentration (0·21 OD_{260}/ml. culture fluid), caused a growth increment 2·5 times as great. Hence the activity of hydrolysates of *s*RNA far exceeded that of the other ribonucleic acid fractions.

The high degree of purity of nucleic acids used in this investigation[3] implies that RNA products themselves rather than nucleotide contaminants are responsible for the cytokinin activity observed. The absence of activity in enzyme hydrolysates of tobacco RNA, and its presence in similar hydrolysates of sheep liver RNA, suggest that a true component of liver RNA is involved rather than an artefact produced by modification of a common nucleotide.

A possible source of the cytokinin activity in liver RNA is a compound of the methylated purine type. Dunn[7] and Bergquist and Matthews[8] have shown that such compounds are particularly abundant in *s*RNA. A number of these compounds have been tested for cytokinin activity and found to be inactive (9-methyladenine, 6-methylaminopurine, 6-dimethylaminopurine) when assayed alone[9]; though 6-methylaminopurine is active at

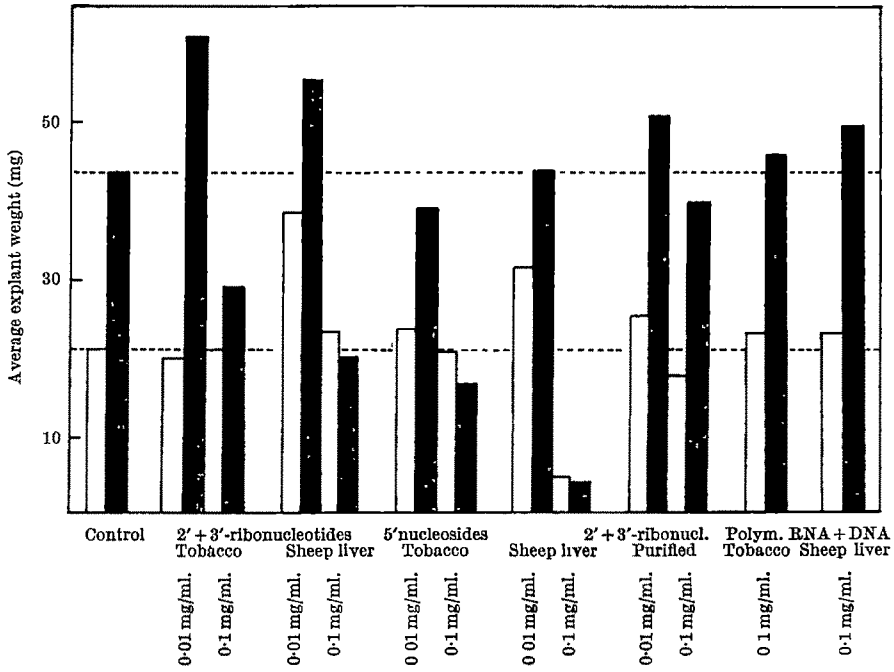

Fig. 2. Average weight of carrot explants after growth in the presence and absence of enzyme and alkaline hydrolysis products of tobacco cell and sheep liver nucleic acids. Kinetin was added to some treatments (0·2 mg/l.). Fractions were assayed at two levels, 0·01 mg and 0·1 mg hydrolysis products/ml. culture fluid. The following fractions were assayed: 2′- and 3′-ribonucleotides (alkaline hydrolysis); 5′-deoxyribo- and ribonucleosides (enzyme hydrolysis); 2′- and 3′-ribonucleotides (purified Pabst products); unhydrolysed (polymeric) nucleic acids (RNA+DNA). □, Fractions plus indole-3-acetic acid alone; ■, fractions plus indole-3-acetic acid and kinetin.

very high concentrations in the presence of adenine[10]. Hall[11] has reported the presence of N^6 aminoacyl adenines in hydrolysates of yeast RNA, but these are alkali-labile and in this study should have been eliminated during hydrolysis procedures. Thus the identity of the active compound or compounds remains unknown.

Cutaneous Melanocyte System of the Indigo Snake *Drymarchon corais*

FOR many years it has been believed that the cutaneous pigment cell system of the so-called lower vertebrates—fishes and amphibians—is mainly a dermal one. As an effector system its function is primarily to show aggregated or dispersed melanin in different hormonal situations, and it does not significantly donate pigment to other tissues. On the other hand, the pigment cell system of birds and mammals has been considered to have primarily a cytocrine function, and to be effectively resident in the epidermis and its derivatives. Here the melanocytes function by donating melanin to contiguous epidermal cells in the integumental epidermis, or in the matrix of hairs or the collars of feathers. It is difficult to understand how the presumably dermal pigmentation of the ancestral vertebrates produced the very elegant epidermal system of birds and mammals, and little descriptive work on the reptile pigment cell system has proved of value in this connexion.

Routine histological sections of the skin of the indigo snake (*Drymarchon corais*) were taken in the course of another investigation. During their analysis, a very odd and apparently new phenomenon was noted. The melanocyte system appears to be mostly dermal although occasionally melanocytes may be seen in the epidermis. The shed skin is, however, quite darkly pigmented and it was considered that there were insufficient epidermal melanocytes to account for this. Close investigation of the histological sections revealed that many and perhaps most of the dermal melanocytes had fine processes which extended across the dermis above the melanocyte layer, through the basement membrane, and into the basal layer of the epidermis. Because of the fine and highly irregular nature of these dendrites, it is very difficult to demonstrate convincingly that any particular dendrite extends from a certain melanocyte up into the epidermis. Sometimes the thicker dendrites (Fig. 1) may be seen to do this, however, and they are occasionally found complete in one 7μ section.

The significance of this finding is rather difficult to assess. It is tempting to suppose that this condition may represent an intermediate between the situation in fishes and amphibians and that in mammals and birds. It has been shown by Szabo (unpublished) and by Hadley (also unpublished) that there is an epidermal melanocyte system in several North American frogs, so that the situation in this snake may be indicative of no more than a possible evolution from a dermal to an epidermal melanocyte system. Nevertheless it raises a number of questions about the presumed inviolability of the basement membrane of vertebrates, and provides a framework for the consideration of vertebrate pigment cell systems as a whole. Further investigations using electron microscopy are in process.

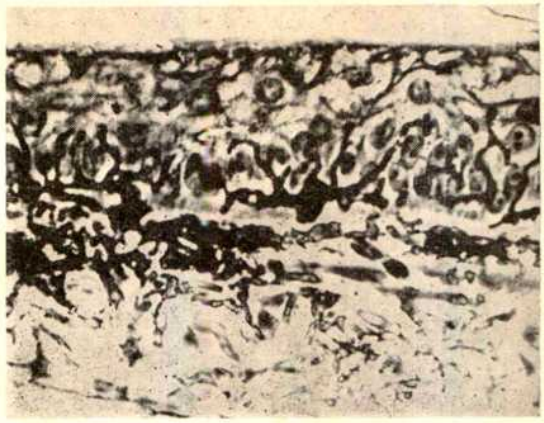

Fig. 1. Part of a 7μ section of *Drymarchon corais* dorsal skin. Dermal melanocytes (*D*) are seen packed with melanin, and parts of epidermal melanocytes (*E*) are sectioned. Note the processes extending across the basement membrane (*BM*)

Echinoid Coelomic Cells

ECHINOID coelomic cells were first described in detail by Geddes[1], who studied the coelomic fluid of *Paracentrotus lividus* and *Echinus esculentus*. Since then, these cells have been the subject of numerous papers, principally descriptions of the cell-types in various species[2–9].

The main coelomic spaces of a regular echinoid are the perivisceral and lantern coeloms and the watervascular system. The perivisceral coelom alone occupies 40–50 per cent of the volume enclosed by the test of a *Psammechinus miliaris* 2–3 cm in diameter, and 70–80 per cent of an *Echinus esculentus* of about 12 cm diameter. The coelomic cells are suspended in the coelomic fluid within these spaces, but some of the cells are amoeboid and are found in other tissues, notably in those of the haemal system. Coagulation and phagocytosis of "foreign" material are two known functions, and other important functions have been attributed to the coelomic cells; however, as has been recently stated[10], their role has not been entirely elucidated.

The present report is based on a cytological study of the cells found in the perivisceral coelomic fluid of *Diadema antillarum* and *Psammechinus miliaris*. The cells can be divided into three morphological types.

(1) Bladder amoebocytes. These are cells usually about 25μ in diameter, with a central mass of endoplasm containing the nucleus. The endoplasm is surrounded by labile bladder-like processes which become filiform as an irreversible coagulation change. Such cells are phagocytic but, as they are so readily involved in coagulation changes, information on taxes or any locomotor activity is difficult to obtain.

(2) Spherule amoebocytes. These are active amoeboid cells about 35μ long when extended. They contain numerous spheroidal inclusions which move freely in the cytoplasm as does the nucleus. In all echinoids studied there were two types of amoeboid cell, one with unpigmented—termed colourless—inclusions, and one with

predominantly red inclusions. Red pigment extracted from coelomic fluid of *D. antillarum* resembled echinochrome A[11], while that from *P. miliaris* had the characteristics of spinochrome E[12]. Cells with yellow-green inclusions were found in *Echinocardium cordatum*, *Spatangus purpureus*, *Brissopsis lyrifera* and in some specimens of *Arbacia lixula*.

(3) Flagellated cells. These are small cells with a cell-body 5–10μ in diameter. These cells invariably move with the flagellum posterior to the cell-body. The nucleus is anterior in position. Cuénot[13,14] at first believed that these flagellated cells were parasitic and assigned them to the genus *Oikomonas* with the specific name *echinorum*. He later expressed doubts as to the validity of this classification[14] and to the parasitic nature of the cells[15]. His doubts have since been confirmed[16]. Besides the occurrence of these cells in every echinoid examined, the position and form of the flagellum, the form and size of the cell-body and the staining reactions indicate that these cells are echinoid rather than parasitic protozoa. Indeed, detached peritoneal cells closely resemble the flagellated cells, which accords with previous views of their origin[1,6].

The composition of the inclusions of the spherule amoebocytes has been investigated. A modification of Liebman's formol-vapour fixation[6] was used, with a method of identifying cells before and after staining. It was found that, contrary to previous opinion[17,18], the red spherules are not acidophilic. Histochemical methods did not detect lipid or protein in particular association with the red spherules. It is possible that previous authors have not made allowances for the reactivity or tinctorial effects of pigment retained after the use of certain fixatives. The spherules were, however, found to be associated with carbohydrate, probably sulphated mucopolysaccharide. Boolootian and Lasker found glycogen in red coelomocytes of well-fed *Strongylocentrotus purpuratus* and this glycogen content was found to diminish on starvation[10]. Glycogen was not detected in spherule amoebocytes of *D. antillarum* or *P. miliaris*.

Kollmann's conclusion[17] that the colourless spherules are albuminous is substantiated by reactions to tests for amino-acids. There is a strong positive reaction to the Adams[19] test for 3-indolyl derivatives. An indolic compound extracted from perivisceral coelomic cells of *P. miliaris* resembles tryptophan in its chromatographic behaviour. The colourless spherules may also be associated with some phospholipid and/or fatty acid.

Some authors have supposed an inadequacy of vascular function in echinoids. Stott[20] believed that the coelomic amoebocytes are responsible for some intracellular digestion in the stomach lumen, and for absorption and transport by migration through the haemal system. He thought that this might be associated with the poor development of the haemal system and lack of a pumping mechanism, which may now be disputed[21–23]. His conclusions on absorption and transport were based on histological examination after injection of iron saccharate into the pharynx of *Echinus esculentus*. I have never observed coelomic cells in the stomach or intestinal lumen of echinoids, except where insufficient precautions have been taken with dissected specimens to prevent contamination by coelomic fluid. Absorption of iron and tryptophan labelled with carbon-14 can be shown to occur without the initial participation of the coelomic cells in *P. miliaris*. An iron-containing pigment occurs in *D. antillarum*[24]. Control specimens of *P. miliaris* showed the presence of small rounded bodies which stained blue after sulphide and ferrocyanide treatment and emphasized the need for careful interpretation of iron saccharate experiments. It was concluded that the coelomic cells are probably not important in digestion or in the initial absorption and transport of nutrients from the gut of *P. miliaris*. The spherule amoebocytes, however, may act as nutrient distributors, as suggested by Boolootian and Lasker[10] for the red cells, moving either with the surrounding fluid or by active amoeboid progression.

There was an apparent reduction in the indolyl content of the coelomic amoebocytes at the onset of gonad maturation in both sexes of *P. miliaris*. It was thought that this might be an indicator of transfer of material. There was no evidence of direct transfer to the gametes, however, as previously described by Liebman in the ovaries of *Arbacia punctulata*[6]. Holland and Giese[25] did not observe direct transfer in the ovaries of *Strongylocentrotus purpuratus*. Thus, although the spherule amoebocytes appear capable of direct transport and may indeed function in this capacity, it has not yet been demonstrated.

This investigation was conducted under the supervision of Prof. N. Millott during the tenure of a Department of Scientific and Industrial Research studentship.

Are Pelagic Diatoms Free from Bacteria?

IN attempting cultures of pelagic diatoms it is the common experience that success is more often achieved when the isolating procedures have not been so thorough as to eliminate all bacteria from the cultures. Although direct nutritional dependence on excretions of the bacteria cannot always be ruled out, physico-chemical effects are probably of greater importance. But do bacteria play the same part in nature? The onset of the spring increase of phytoplankton in coastal waters can seldom be traced to simple causes. It is often observed to follow a period of quiet fine weather when a major factor is undoubtedly the absence of vertical mixing. Light may be all that is needed to trigger the diatom growth; but it is also conceivable that the winter water requires "conditioning" before growth can start, and the slight increase of temperature at the surface during a fine spell increases bacterial metabolism sufficiently for this. Such an effect will be greatest when the association between bacteria and diatoms is most intimate—that is, between any epiphytic bacteria and their host cells. It is not clear from the literature, however, how close is the association between bacteria and phytoplankton in the sea. Marine bacteria are nearly always associated with particulate matter[1,2], and there is often a correlation between the abundance of bacteria and living diatoms[2,3]. Nevertheless, live plankton diatoms do not seem to harbour a heavy epiphytic flora, as do many freshwater

algae. On the contrary, the cells usually appear to be remarkably clean. There are, however, no published observations, although other evidence[4,5] suggests that diatoms may have antibiotic activity.

We have attempted by cultivation and by direct observation to determine the extent to which bacterial infestation occurs on the cells of two species of diatom. We picked specimens of the large winter species *Coscinodiscus concinnus* from tow nettings over a period of several months during the winter of 1963, carried them through six washes of sterile sea water and placed them singly into cultures of the diatom *Phaeodactylum tricornutum* in a liver infusion/soil extract/sea-water medium (*E*6, our medium for routine sterility testing of algal cultures[6]). *Ph. tricornutum* was provided as an alternative substratum, since the object was to isolate bacterial strains intimately associated with, and therefore possibly dependent on, the live cells, whereas most *C. concinnus* cells fail to survive the washing procedure. *C. concinnus* is so large that it was not possible to avoid transferring a considerable volume of water along with the cells; we therefore set up controls at the same time by transferring to *Phaeodactylum* cultures a little of the wash water from the final bath, but without the *Coscinodiscus*. The results of this experiment (Table 1) show that, if any bacteria were associated with the diatom, either they failed to survive the transfer, which is improbable, or that the association was loose enough to allow their removal simply by passage through sterile sea water.

Table 1. BACTERIAL CONTAMINATION IN CULTURES OF *Phaeodactylum tricornutum* IN WHICH HAD BEEN PLACED (*a*) SINGLE WASHED CELLS OF *Coscinodiscus concinnus*, OR (*b*) A LITTLE WATER FROM THE LAST WASH BATH

	Presence of bacteria		
	+	−	
(*a*) With *Coscinodiscus*	12	291	303
(*b*) Control	9	221	230
	21	512	533

Satisfactory direct observation to determine the incidence of attached bacteria could not be made on a sufficiently large sample of *C. concinnus*, but we made some phase contrast counts on *Skeletonema costatum* in the following spring. During the diatom increase there were between three and five bacteria attached to each hundred *Skeletonema* cells, while within a week of the diatom maximum the count had gone up to thirty-two per hundred cells. We repeated the phase contrast counts, but in greater detail, the following year, examining some hundreds of cells on each occasion. The result was essentially the same (Fig. 1); the attached bacterial cell/diatom cell ratio remained low and remarkably constant throughout the phase of diatom multiplication and for several days of the stationary phase. These bacteria appear to have been multiplying at the same rate as the diatoms; alternatively, the cells failing to resist bacterial attachment were a constant proportion of the whole. On the sixth day of stationary phase the bacterial count suddenly began to mount, but by then the diatoms had taken on the unhealthy aspect of a population obviously in need of rejuvenation by auxospore formation, and dead cells had begun to appear in the chains, later presumably to be colonized by saprophytic bacteria. Waksman *et al.*[2] have previously recorded an increase in bacterial activity in the later stages of a (laboratory) diatom growth. The spring increase in the Clyde in 1965 was early and rather light, being terminated either by depletion of nutrient or by exhaustion resulting from the absence of auxospore formation, but not by turbulence or by grazing as the water was calm and zooplankton (*Calanus*) were few and had scarcely started to feed.

Both our sets of observations, therefore, lend support to the idea that healthy pelagic diatoms are virtually free from bacteria and they invite speculation about the defence mechanism of the diatom. If our results are typical, epiphytic bacteria are certainly too few to influence the growth of *Skeletonema*. This conclusion, of course, does not touch the wider issues of microbial/diatom interactions in our waters, for *Skeletonema* merely forms the early spring increase, the first wave of diatom growth, whereas the subsequent history of the water is likely to be influenced by the enormous increase in the numbers of the bacteria as the spring advances.

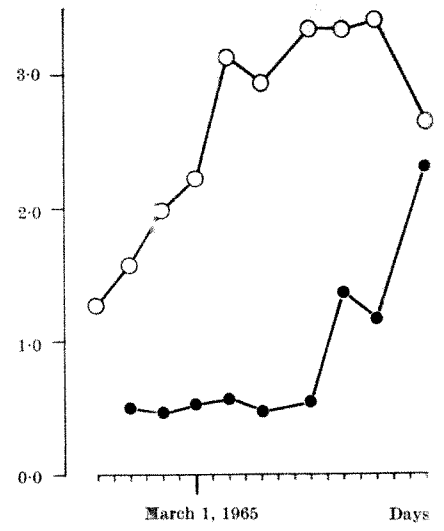

Fig. 1. Time course of the spring increase of *Skeletonema costatum* in the Clyde in 1965. Open circles, $\log_{10}$ diatom cells per ml. from straight samples from Keppel Pier taken at mid tide on the flow. Closed circles, numbers of attached bacteria per ten diatom cells. The water temperature lay between 5·4° C and 6·7° C throughout the period of observation.

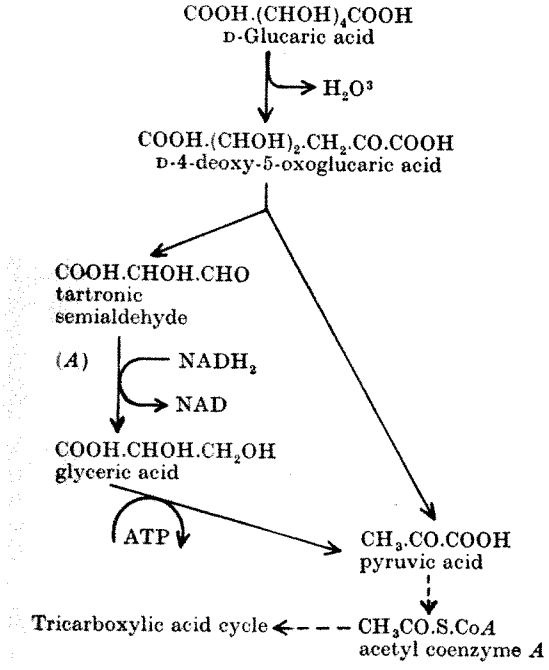
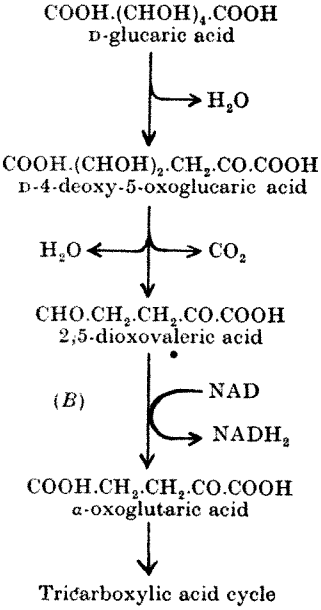
MICROBIOLOGY

D-Glucarate Catabolism by Pseudomonadaceae and Enterobacteriaceae



D-GLUCARIC acid, the naturally occurring dicarboxylic acid analogue of D-glucose, can be utilized as the sole source of carbon and energy by many Enterobacteria[1] and Pseudomonads[2]. Blumenthal and Fish[1] found that the induced catabolic pathway shown in Scheme 1 operated in all the Enterobacteria which they investigated (see Table 1).

This pathway (here identified as the glycerate pathway) involves tartronic semialdehyde (HCO.CHOH.COOH) derived from one half of the D-glucarate molecule as a precursor of pyruvate. When cell extracts are incubated with D-glucarate, tartronic semialdehyde accumulates because its conversion to glycerate requires substrate levels of reduced nicotinamide-adenine dinucleotide (NADH). Since tartronic semialdehyde, or its spontaneous decarboxylation product, glycolaldehyde ($HCO.CH_2OH$), forms an α-*bis*-2,4-dinitrophenylhydrazone with a characteristic purple colour in alkali (λ_{max} 550–565 mμ)[5], its accumulation can be detected and used as a diagnostic test for the operation of this pathway in a test organism.



An alternative induced pathway has been reported for a single *Pseudomonas* strain by Dagley and Trudgill[6]. In this pathway, the α-oxo-glutarate pathway, D-glucarate is not cleaved to form two C_3-units but undergoes two dehydrations and a decarboxylation to form 2,5-dioxovaleric acid (Scheme 2).

As the oxidation of 2,5-dioxovalerate to α-oxoglutarate requires substrate amounts of nicotinamide-adenine dinucleotide the 2,5-dioxovalerate accumulates when cell extracts are incubated with D-glucarate[6]. Like tartronic semialdehyde this compound forms a *bis*-2,4-dinitrophenylhydrazone. In contrast to the derivative of tartronic semialdehyde, however, it gives a brown colour in alkali (λ_{max} 433 mμ)[6].

To investigate the frequency of the α-oxoglutarate path way in Pseudomonads, micro-organisms forming morphologically distinct colonies and capable of growth in D-glucarate as source of carbon were isolated by enrichment culture from soil and mud samples gathered in the Aberystwyth area. *Pseudomonas* strains isolated by other workers and found to be capable of growth on D-glucarate were also used. The micro-organisms were grown aerobically in shake culture in a D-glucarate mineral salts medium[6]. They were collected by centrifugation, disrupted by sonication and cell extracts clarified by centrifuging. Finally, extracts were incubated with D-glucarate at 30° C. The pathway followed was elucidated from the nature of the *bis*-2,4-dinitrophenylhydrazone formed by the reaction product. It was found that all the *Pseudomonas* strains investigated utilized the α-oxoglutarate pathway (Table 2), whereas the three strains of *Enterobacteria* which had been isolated followed the glycerate pathway described by Blumenthal *et al.* (Table 1).

Scheme 1. D-Glucarate catabolism by the glycerate pathway (after Blumenthal and Fish (ref. 1)). Dehydration yields predominantly the 4-deoxy-5-oxoglucaric acid (Blumenthal and Jepson (ref. 3)). (*A*) Catalysed by tartronic semialdehyde reductase (ref. 4).

Scheme 2. D-Glucarate catabolism by the α-oxoglutarate pathway (ref. 6). (*B*) Catalysed by 2,5-dioxovalerate dehydrogenase (ref. 6).

Table 1. ORGANISMS UTILIZING THE GLYCERATE PATHWAY OF D-GLUCARATE CATABOLISM

Source	Organism
Soil sample *A*	*Aerobacter aerogenes*
Soil sample *B*	,, ,,
Soil sample *C*	,, ,,
Data of Blumenthal and Fish[1]	*Escherichia coli**
	Escherichia freundii
	Erwinia caratovora
	Aerobacter aerogenes
	Paracolobactrum arizona
	Salmonella typhosa
	Klebsiella pneumoniae

* Nine strains.

Spectrophotometric enzyme assays provided further evidence that the pathways could be attributed to the organisms listed in Tables 1 and 2: only organisms utilizing the α-oxoglutarate pathway possessed high levels of 2,5-dioxovalerate dehydrogenase[6]. Tartronic semialdehyde reductase[4] was present at high levels in those micro-organisms which were operating the glycerate pathway.

Table 2. ORGANISMS UTILIZING THE α-OXOGLUTARATE PATHWAY OF D-GLUTARATE CATABOLISM

Thus the evidence so far accumulated suggests that on these metabolic grounds a division can be drawn along the boundary between the two families of bacteria. Besides the obvious catabolic reaction differences between the two pathways, differences of a more fundamental nature are apparent. The two pathways are in a sense opposites. The glycerate pathway cleaves D-glucarate into two C_3-units both of which yield acetyl coenzyme *A* by way of pyruvate; the necessary provision of C_4-compounds to operate the biosynthetic reactions of tricarboxylic acid cycle is probably achieved by anaplerotic fixation of carbon dioxide on to phosphoenol pyruvate[11]. The formation of α-oxoglutarate in the alternative pathway can provide directly tricarboxylic acid cycle intermediates for biosynthesis. For complete oxidation of the α-oxoglutarate, a proportion of the oxaloacetate formed from it must be converted to acetyl coenzyme A. This is

presumably derived from pyruvate formed by the action of oxaloacetate decarboxylase[12].

CYTOLOGY

Collagen in Normal Mouse Glomeruli

THE mesangial region of the normal renal glomerulus has been the subject of controversy for many years and is the site of collagen production in some diseases[1,2]. Although there have been many investigations in a variety of animals, we are aware of only one published account which has described collagen fibrils in the normal glomerulus. These were described in the rat[3]. During investigations of experimental renal amyloidosis in the mouse we had cause to examine the glomeruli of normal animals. Careful search of the mesangial regions revealed the presence of typically striated collagen fibrils with periodicity 500–600 Å and showing intraperiod striations. Fig. 1 shows parts of two mesangial cells (the arrows point to collagen fibrils). Fig. 2 is a higher power electron micrograph of the area indicated between the arrows in Fig. 1. The tissue was fixed in buffered osmium tetroxide solution, embedded in 'Araldite', and after sectioning stained for 1 h with 2 per cent phosphotungstic acid dissolved in absolute alcohol.

Fig. 1. Portions of three mesangial cells. Arrows indicate the position of collagen fibrils. (× 10,000.)

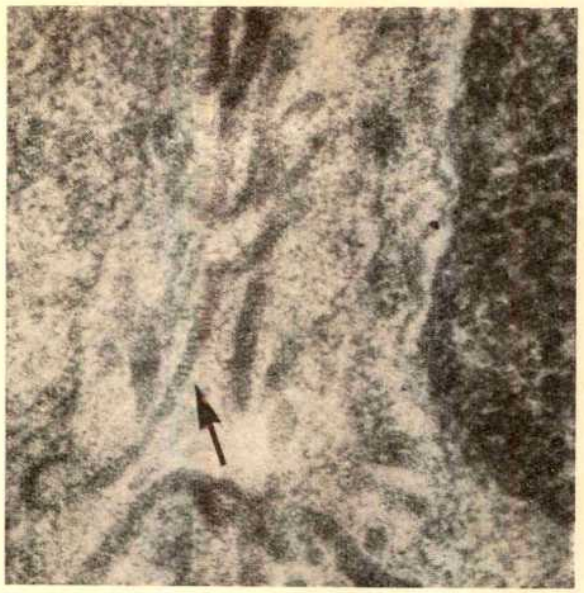

Fig. 2. Higher power electron micrograph of part of Fig. 1. Arrow indicates intraperiod striations. (× 80,000.)

The presence of collagen fibrils within the normal mouse glomerulus establishes that these are not restricted to the rat. This emphasizes the potential functional importance of the mesangial cells. Although such small numbers of collagen fibrils could not offer much structural support to the glomerulus, their presence is indicative of the mesenchymal properties of the mesangial region and its possible role in disease processes.

Modification of Relative Mutagenic Efficiency in Barley of Mesyloxy Esters by Different Treatments

THE mutagenicity of mesyloxy esters of differing chemical structure has been studied in *Drosophila*, and the marked differences observed have been attributed to differences in the reactive alkyl group and the non-alkylating "prosthetic" parts of the compounds[1]. Relationships between the chemical structure and the biological effects of different monomesylates have also been studied in barley[2]. Although the qualitative and the quantitative differences in the biological effects, including chromosome breakage and mutation rates, produced by this group of compounds have been attributed to a correlation between structure and activity, very little attention has been paid to the physical factors which may influence the reactivity. By "physical" we mean such factors as temperature and hydrogen ion concentration of the treatment solutions, which may influence the reactivity, functionality, stability and the rate of diffusion of a chemical, and which in turn may modify its biological effects. We have therefore studied the modifying effects in barley of temperature and hydrogen ion concentration on various biological effects produced by the three mesyloxy esters—ethyl methane-sulphonate (EMS), methyl methane-sulphonate (MMS) and 1,4-dimethylsulphonoxybutane (myleran). The compounds have different reactive alkyl groups. The present report summarizes data relating to the effect

Table 1. FREQUENCY OF SOMATIC CHROMOSOME BREAKAGE INDUCED BY EMS, MMS AND MYLERAN IN VARIOUS TREATMENT CONDITIONS OF TEMPERATURE AND *p*H (BREAKS/CELL)

* χ^2_{EMS} for 9·2 and 3·5 *p*H at 32° C = 5·74 significant at the 5 per cent level.

† χ^2_{MMS} for 9·2 and 3·5 *p*H at 32° C = 4·828 significant at the 5 per cent level.

Table 2. CHLOROPHYLL MUTATION RATES INDUCED BY EMS IN VARIOUS TREATMENT CONDITIONS OF TEMPERATURE AND *p*H (AS PERCENTAGES OF M_1 SPIKES SEGREGATING)

	Temperature			
*p*H	0° C	18° C	32° C	Mean
9·2	16·15	21·71	42·19*	26·68
7·0	12·87	23·21	39·18	27·97
3·5	12·45	23·65	32·82	22·97
Mean	13·82	22·85	38·06	

* Effect of *p*H is significant at 32° C.

Table 3. CHLOROPHYLL MUTATION RATES INDUCED BY MMS IN VARIOUS TREATMENT CONDITIONS OF TEMPERATURE AND *p*H (AS PERCENTAGES OF M_1 SPIKES SEGREGATING)

	Temperature			
*p*H	0° C	18° C	32° C	Mean
9·2	9·31	16·34	36·06*	20·58
7·0	8·22	18·15	29·75	18·71
3·5	8·96	17·61	23·52	16·70
Mean	8·84	17·34	29·78	

* Effect of *p*H is significant at 32° C.

of temperature and *p*H on the frequency of chromosome breakage in somatic cells and on chlorophyll mutation rates induced in barley by the three chemicals.

Dry resting seeds of a hulled variety of *Hordeum vulgare* (c.v. *NP* 104) were treated with three mutagen solutions prepared in buffers adjusted to acid (*p*H 3·5), neutral (*p*H 7·0) and alkaline (*p*H 9·2) conditions. Three identical treatments were carried out at 0°, 18° and 32° C for 12 h. Details of treatment and the methods of estimation of chromosome breakage and mutation rates are described elsewhere[3]. Because the comparisons of biological effects could be made for 0·3 per cent of EMS, 0·03 per cent of MMS and 40 mg/100 ml. of myleran at all temperature and *p*H levels, the results for these concentrations alone are summarized in Tables 1, 2 and 3. Myleran induces chlorophyll mutations with very low frequency when dry seeds are used for mutagenic treatments. Thus, for the purpose of comparison, rates observed for previously soaked seeds are given.

A highly significant response to temperature has been observed in all cases, as is evidenced by both chromosome breakage and mutation rates (Tables 1, 2 and 3). The response to *p*H was significant at higher temperatures, especially with EMS and at high concentrations of mutagen. A comparison of the biological effects at different temperature and *p*H indicated that in alkaline conditions the frequency of chromosome breakage is appreciably lower than with acid *p*H, while the frequency of chlorophyll mutations is high (Tables, 1 2 and 3). The converse was observed in acid conditions. This relationship was strikingly similar for all the three chemicals.

The increase in the frequency of chlorophyll mutations in alkaline conditions may be explained by the reduction of injury to the seeds likely to be caused by the acidity of hydrolysed mutagen solutions, which may result in higher recovery.

The specificity of the mutagen enhanced by *p*H, which was evident from the high frequency of chromosome breakage at low *p*H, may also be responsible for the observed differences.

From this study it appears that the production of mutations and chromosome breakage are independent events, and that their relative proportions vary with the treatment conditions to a considerable extent. Analysis of several chlorophyll mutations for their karyotypes indicates no detectable chromosomal change in the complement. The incidence of seed sterility at these doses was roughly 50 per cent in all cases, so that the elimination of mutated cells at low *p*H appears not to be operative.

The three chemicals fall into three distinct categories, on the basis of their ability to induce chromosome breakage and mutations, (*a*) agent that induces a high frequency of mutation accompanied by a low frequency of chromosome breakage (EMS); (*b*) moderately high frequency of mutation accompanied by a high frequency of chromosome breakage (MMS); (*c*) very low frequency of mutation accompanied by a high frequency of chromosome breakage (myleran). It appears that by appropriate manipulation of treatment conditions, any one of these biological effects may be produced in preponderance so as to enhance the mutagenic efficiency of these chemicals.

PHYSIOLOGY

Slow Response of Crustacean Nerve Fibre in a Solution Deficient in Chloride Ions

IN skeletal muscle fibres the permeability of chloride ions is higher than the permeability of potassium ions[1]. Deficiency of chloride ions leads to a prolongation of the action potential, suggesting that the repolarization phase depends to some extent on anion-current[2]. In the nerve fibre, however, the permeability of chloride ions is relatively low in the resting state and chloride ions are not important for the repolarization phase of the action potential (for example, see ref. 3 for squid giant axon and ref. 4 for Ranvier node of frog).

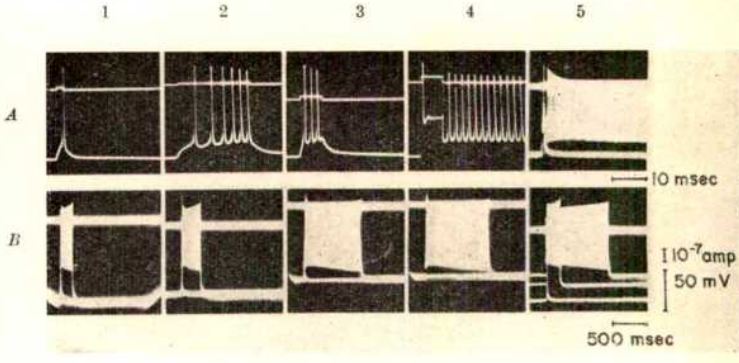

Fig. 1. *A*1 and *A*2, Responses in normal solution (lower traces). 3 min after the chloride had been replaced with ferrocyanide a weak stimulus produced the same response as did the control, but a strong stimulus produced a slow response with repetitive firing (*A*4). *A*5 was taken 5 min after chloride had been replaced with ferrocyanide (the stimulus was the same as that in *A*4, but the record was taken by a sweep speed ten times slower). The membrane remained in a depolarized state even after the repetitive firing ceased. Row *B* shows the effect of hyperpolarization on the slow response. Stimulus intensity and duration were throughout the same as in *A*4 (5×10^{-8} amp, 7 msec). Conditioning hyperpolarization was reduced from *B*1 to *B*4. In *B*5, three responses were superimposed at different hyperpolarization levels. The time scale for *A*5 is 100 msec.

When chloride in the medium surrounding a crustacean nerve fibre is replaced by glutamate, ethanesulphonate or ferrocyanide, it is possible to elicit a slow response to electrical stimulation. The response is a prolonged depolarization similar to that seen in potassium-rich media[5] and is usually accompanied by repetitive spikes. This suggests that there is normally an increase in the permeability of chloride ions and an inward movement of these ions during the falling phase of the action potential. In media free of chloride ions there would seem to be an outward movement of the anion with the formation of a plateau.

Single motor nerve fibres, fast closer or opener fibres, were dissected from the meropodite segment of the walking limb of the crab, *Callinectes sapidus*, collected in the Gulf of Mexico. The techniques used for recording and stimulation were the same as those previously described[6].

Figs. 1 and 2*A* show examples of responses to electrical stimulation in a ferrocyanide solution free of chloride ions, and Fig. 2*B*, those in a glutamate solution free of chloride ions. When the normal solution was replaced with a solution deficient in chloride ions, the membrane potential remained constant for a few minutes, then gradually decreased. The response to stimulation was unchanged for a few minutes (*A*3 in Fig. 1), but then a prolonged depolarization was produced during or after stimulation as shown in *A*4 and 5 in Fig. 1 and Fig. 2*A*. The slow response was usually accompanied by repetitive spike activity. When the magnitude of the slow response was small the spike activity was maintained as long as the slow response continued (Fig. 1 and Fig. 2*A*), but when the slow response was large the spike activity stopped although the depolarization persisted (Fig. 2*B*). The spike shape remained normal throughout these periods of repetitive activity. The peak potential reached during the spike depended on the magnitude of the slow response. As the slow response developed and then decreased, the peak potential decreased and then increased. In a solution free of chloride ions, as the membrane potential fell spontaneous repetitive firing was often initiated at critical firing level and was maintained for long periods of time (Fig. 2, *A*3).

During a slow response without spike activity, cathodal stimulation could no longer produce an active response. A conditioning hyperpolarization, however, restored the excitability of the membrane. Thus the slow response was easily produced by outward current pulses given during the passage of conditioning inward current. As seen in Fig. 2*B*, the repetitive spike activity was reactivated during (*B*1 and 2) or after (*B*3) hyperpolarization. The duration of the slow response depended on the membrane polarization as reported for the slow response observed in potassium-rich media[5]. Hyperpolarization made the response shorter (Fig 1*B*).

The substitution of glutamate and ethanesulphonate for chloride produced more or less similar effects to those of ferrocyanide solution. When thiocyanate was substituted for chloride, neither the slow response nor sustained repetitive firing was seen.

The slow response obtained in solution deficient in chlorine ions cannot result from the decreased calcium ion activity of the solution. Reducing calcium concentration in solution with a normal chloride content did not produce the same kind of response. High calcium concentration, however, reduced the slow response. The slow response in solutions deficient in chloride ions differs from the slow response in solutions rich in potassium ions because the latter response does not show associated repetitive firing.

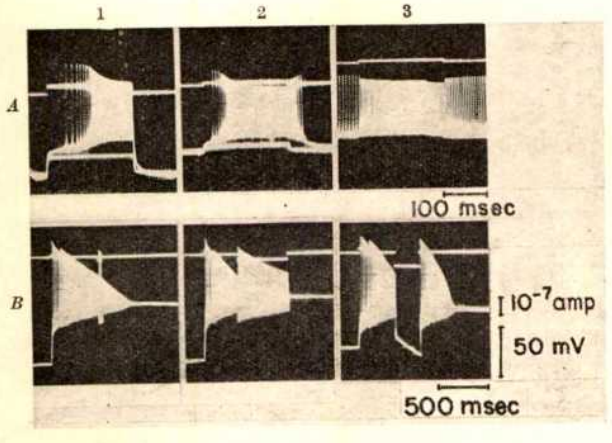

Fig. 2. *A*, The slow responses produced by long stimulating pulses (about 200 msec) in chloride-free ferrocyanide solution. *A*1, 1 min; *A*2, 3 min; *A*3, 5 min after replacing the solution. Repetitive firing was continuous for many minutes in *A*3. *B*, The effect of hyperpolarization during the slow response produced by a 100 msec cathodal pulse in a glutamate solution free of chloride ions. Note reactivation of repetitive spike activity during (*B*1 and *B*2) or after hyperpolarization (*B*3).

Axon Hillock of Neurones of the Lateral Vestibular Nucleus of the Ox

The axon of vertebrate neurones may arise either from the soma or from a dendrite. When it arises from the soma it may arise directly, as in the Purkinje cells[1], or from a specialized region known as the axon hillock. Little appears to be known regarding the electron micrographic appearance of this region. Electron microscopical studies on isolated neurones facilitate the identification of specific structures, and during our investigations of neurones isolated from the lateral vestibular nucleus of ox (*Bos taurus*) brain we have been able to obtain sections through the axon hillock and the non-myelinated part of the axon.

The neurones were isolated from freshly slaughtered animals by the method previously described[2] and were prepared for electron microscopy in polythene planchets[3]. The observations to be described here were made on cells which had either been isolated in Ringer–Locke solution and fixed in phosphate-buffered glutaraldehyde followed by 1 per cent veronal-buffered osmium tetroxide, or had been isolated in 0·9 per cent sodium chloride containing 0·25 mg, 0·55 mg, or 1·1 mg gangliosides per ml., and fixed in 1 per cent veronal-buffered osmium tetroxide. After dehydration in a graded series of ethanol, the cells were stained with 1 per cent phosphotungstic acid and embedded in 'Araldite'. Isolation, fixation and dehydration were carried out at 4° C.

The axon hillock was identified positively by tracing the origin of the axon from the soma through the non-myelinated part to the beginning of myelination. On account of the size of the structure we have not as yet obtained a section showing the whole of it. Typical pictures of the origin of the axon are shown in Figs. 1 and 2. On the right of Fig. 1, part of the slope of the cone can be seen, and on the left, part of the hillock is shown running into the non-myelinated part of the axon. Fig. 2*a* shows the central core of the axon hillock. The increased density of packing of the neurofilaments, their parallel alignment, and the absence of Nissl substance, characteristics of this region noted by Cajal[4], are clearly illustrated

in the figures. The tubular structures appearing at the bottom of Fig. 1 have been observed frequently in the vicinity of the axon hillock, but we have not as yet been able to determine their relationship to the rest of the structure.

In one case we were able to obtain longitudinal sections through the non-myelinated part of the axon from the point of origin to the start of myelination and thus obtained a measurement of the length of the initial segment (axon hillock plus non-myelinated axon). The initial segment was 50μ long—a figure which is compatible with previous estimations of its length in other neurones[5].

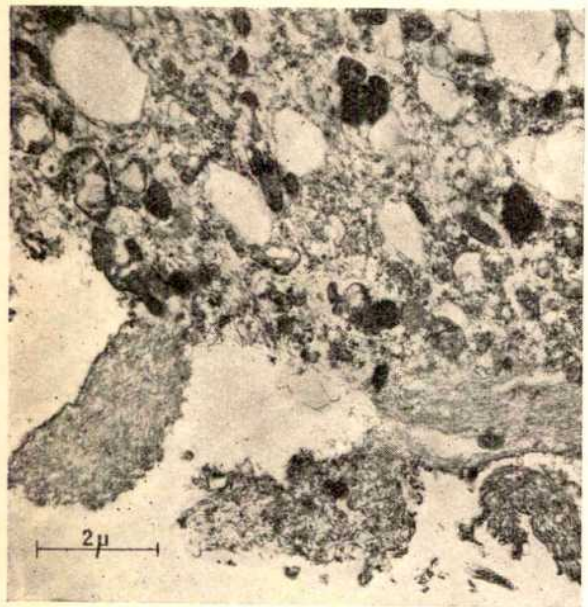

Fig. 1. Part of the cone of the axon hillock.

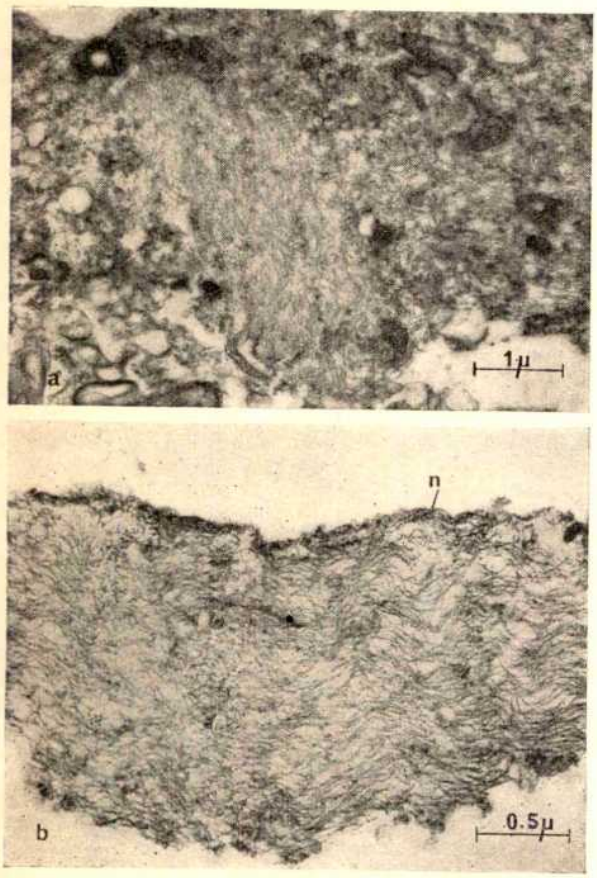

Fig. 2. *a*, Central core of the axon hillock. *b*, Part of the axon hillock at higher magnification showing densely packed neurofilaments (*n*) at the surface.

The most striking electron microscopical feature of the axon hillock is the denseness of the surface. At low magnifications this gives the appearance of a thickened surface membrane (Fig. 1), but at higher magnifications it can be seen that this effect is due to the close packing and alignment of the neurofilaments at the surface (Fig. 2*b*). Unlike the surface of the soma (and most dendrites) which varies in appearance with the composition of the isolation medium, and is very disrupted when cells are isolated in Ringer–Locke solution, this appearance of the axon hillock is consistent. The reason for this is not known. It may indicate an intrinsic difference in the molecular structure of this region, and/or it may be due to there being fewer nerve endings so that the surface is not disrupted by their removal[2,3].

Although it is not known whether the axon hillock of neurones from other regions of the brain presents a similar electron micrographic image, the observations reported here present criteria for the identification of the initial segment in these cells (and possibly others) and should facilitate further observations on this region. Further observations are in progress aimed at clarifying the situation regarding the possible difference in the surface structure, and determining whether or not nerve endings occur on the hillock.

We thank Mr. S. Waterman for assistance with photography, and the Nuffield Foundation for financial support.

Oestrus and Ovarian Morphology in Gilts following Treatment with Orally Effective Steroids

THIS communication describes an experiment carried out to evaluate the effect of two combinations of progestin and oestrogen treatments on oestrus and ovarian morphology in gilts.

Attempts to synchronize oestrus in gilts with orally effective progestins have generally resulted in a large proportion of cystic ovarian follicles[1–3]. The level of progestin treatment has also been reported to affect the occurrence of cysts[1,4]. Addition of a gonadotrophin to the treatment regime may be beneficial in reducing cystic conditions[1,4], indicating that an insufficiency of ovulating hormone may be involved in the formation of cysts.

Forty gilts (Duroc, Hampshire, Yorkshire and cross-bred) were used in a trial conducted during May–July 1963. Gilts were checked daily for the occurrence of oestrus with vasectomized boars before treatment. All animals had exhibited at least one oestrous period during this interval, and about half had experienced a complete oestrous cycle (18–23 days in length). The animals were divided into four groups on the basis of breed, weight and stage of oestrous cycle. Two groups were administered daily 25 mg 6-chloro Δ^6-17 acetoxyprogesterone (CAP) per gilt and 1 mg ethynyl oestradiol 3-methyl ether (EE) per gilt. The remaining two groups received daily 125 mg CAP per gilt and 5 mg EE per gilt. These hormones were mixed in 6 lb. of the normal ration and administered for 10 days in individual feeders to ensure that each animal would consume the predetermined amount of CAP : EE.

Three days after termination of CAP : EE feeding, gilts receiving the 25 : 1 combination were injected with 500 I.U. human chorionic gonadotrophin (HCG) and 1 mg oestradiol benzoate (ODB). HCG and ODB were administered intramuscularly in the loin area as separate injections, HCG in 4 ml. physiological saline and ODB in 4 ml. sesame oil. The remaining two groups (125 : 5 CAP : EE combination) received the identical HCG–ODB injections, but the interval between the last CAP : EE feeding and the injections was 5 days. All gilts were checked daily for symptoms of oestrus with intact or vasectomized boars during the experimental period. Animals were slaughtered 7 days after the HCG–ODB injections. The reproductive tracts were then recovered and evaluated.

Both CAP : EE treatment combinations were effective in inhibiting oestrus during the feeding phase. Only half the gilts, however, were observed to be in heat following treatment (twenty out of forty, Table 1). The low level of CAP : EE resulted in nearly twice as many gilts in oestrus as the high level (thirteen compared with seven), but this difference was not statistically significant ($P \sim 0{\cdot}10$). Gilts were observed in oestrus approximately two days following the HCG–ODB injections (range of 1–4 days). Neither the interval to oestrus nor the length of oestrus was significantly affected by treatment.

Examination of the ovaries revealed that 72 per cent of all gilts had one or more cystic follicles (those 15 mm or greater in diameter). Although the number of gilts with cystic follicles did not differ appreciably between treatments, the number of cystic follicles per gilt was significantly different ($P < 0{\cdot}05$). Gilts receiving the higher CAP : EE level had fewer cystic follicles than those receiving the lower level. This difference was also reflected in total ovarian weight ($P < 0{\cdot}05$). The average number of follicles 2–14 mm in diameter was nearly twice as great for the 125 : 5 treatment combination. The average size of these follicles was about 5 mm in both groups. Although the number of these "moderate" sized follicles did not differ significantly between the two treatments, it does suggest that the occurrence of cysts reduces the number of follicles in this classification.

The ovulation rate, as reflected by number of corpora lutea and corpora haemorrhagica, was 13·5 in the 25 : 1 CAP : EE group and 16·2 in the 125 : 5 group. More corpora haemorrhagica were observed in the higher CAP : EE group (not statistically significant), suggesting that ovulatory response was delayed somewhat on this treatment. Results summarized by breed groups are presented in Table 2. The small number of animals involved in two breed groups (Hampshire and crossbred) limits the conclusions which can be drawn concerning breed differences. In general, crossbred gilts differed markedly from the other groups in most of the traits evaluated. Larger numbers would be required to assess the real significance of this apparent difference.

The CAP and EE utilized in this trial were kindly provided by Eli Lilly and Co., Greenfield, Indiana.

Guinea-pig Mast Cells and Age

IN the course of certain experiments on guinea-pigs, it was considered relevant to examine the mast cell population with reference to the age and degree of sexual maturation reached by the animals.

Guinea-pigs were killed by cervical section, and their abdomens opened by a median incision. The greater omentum was spread thinly on a slide and excess fat removed. The slides were then subjected to the technique of Shelley and Florence[1] which involved fixation with ice-cold ethylene glycol monomethyl ether as these mast cells are water soluble, and staining with 0·25 per cent aqueous methylene blue. After dehydration and before mounting in 'Depex', it was necessary to vary the time in xylol depending on the amount of fat present. Mast cells were found in greatest numbers in the perivascular and adjacent fat tissue; ten fields representing 7·35 mm² were counted for these cells. Similar methods were used by Cairns and Constantinides[2], and Koltai, Minker and Deak[3].

The average count with ten female adult guinea-pigs was 37 ± 2·5 mast cells, while immature female animals had an average count of 110 ± 5·9 cells. When bilateral oophorectomy was performed, and counts made 2–3 months later, an average figure of 42 ± 5·5 mast cells was obtained. Statistically, this is not significantly different from the value found for the adult unoperated animals. Comparable results were met in the male animals, adults having average counts of 55 ± 3·2, immature 104 ± 3·6 and orchidectomized guinea-pigs 51 ± 4·5 mast cells. The difference between the figures obtained from normal male and orchidectomized animals was not significant. These findings suggest that the sex hormones are probably not important in this connexion especially as there is no apparent change in the count with sexual maturity. My conclusion that oophorectomy fails to influence the mast cell count is supported by Harvey[4], who also found that oestrogens given to spayed female hamsters did not have any effect on the population of mast cells. Constantinides and Rutherdale[5], working on rats, reported that neither testosterone nor orchidectomy changes the cardiac mast cell population in the male. Similarly, in the female, the cardiac mast cell count is not affected by oophorectomy or by the injection of progesterone.

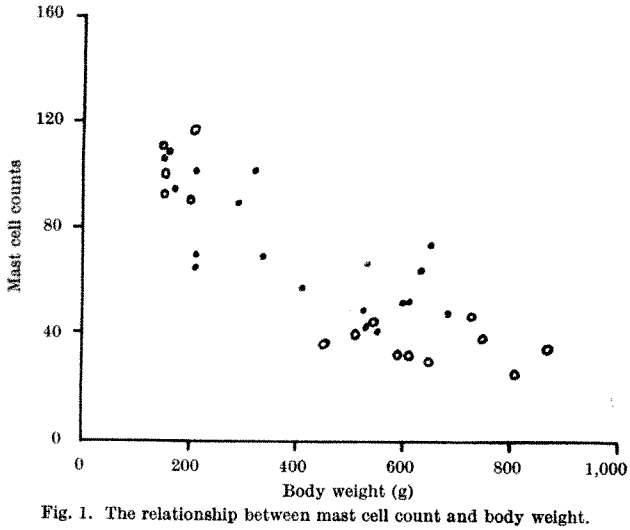

Fig. 1. The relationship between mast cell count and body weight.

When the mast cell counts of the guinea-pigs were plotted against body weight, a rectilinear relationship was found (Fig. 1). The correlation coefficient for the female animals was 0·89 and for the males 0·77. Selye[6], in his intensive bibliography, presents no constant picture of the mast cell count in the ageing process, and makes no mention of it in guinea-pigs. Because weight gives a reasonable estimate of the age of these animals, my results suggest that there is a significant fall in the omental mast cell count with age within the range studied.

Metabolic Differences between Dietary Liquid Glucose and Sucrose

IN the fifty years since Higgins[1] obtained evidence that fructose has a greater tendency to change into fat in the body than has dextrose, more evidence has accumulated, much of it in the past few years, to show that lipid metabolism in man and experimental animals is affected differently by different carbohydrates[2–5]. Recently, it was found that substitution of sucrose for starch in the diet of weanling and three month old rats caused metabolic changes[6], and that diets containing sucrose, and more especially fructose, increased plasma cholesterol levels and carcass and liver fat of adult rats compared with diets containing dextrose or liquid glucose or a standard laboratory diet[7].

Long-term feeding trials in man under strict experimental conditions are difficult, but studies of primates are desirable to investigate further the possible connexion between dietary sucrose and ischaemic heart disease[8–10]. The susceptibility of baboons to develop atherosclerosis has been demonstrated[11], and at present we are using mature baboons (*Papio anubis* = *P. doguera*) for long-term feeding trials in which high carbohydrate diets are being compared. In preliminary studies with a small group of twelve animals, differences have been found between baboons fed liquid glucose and those fed sucrose; the present findings support the accumulating evidence that dietary carbohydrates are not all metabolically equivalent.

Sexually mature animals weighing about 9·5 kg were fed for 26 weeks on diets containing 74 per cent available carbohydrate, either as spray-dried liquid glucose BPC (ref. 12) (an aqueous preparation of partially hydrolysed starch) or as sucrose, or a control diet containing 47 per cent available carbohydrate mainly as starch but with some sucrose (4·5 per cent) and liquid glucose (4·5 per cent). The results are summarized in Table 1.

Table 1. MEASUREMENTS ON BABOONS FED LIQUID GLUCOSE, SUCROSE OR CONTROL DIETS FOR 26 WEEKS*

	Liquid glucose	Sucrose	Control
Total serum lipid, mean value over 26 weeks (mg/100 ml.)	347 ± 29	458 ± 27	341 ± 22
β-lipoprotein fraction (precipitation index (ref. 13)), mean value over 26 weeks	1·3 ± 0·1	1·8 ± 0·1	1·5 ± 0·1
Results at end of experiment			
Energy value of food consumed (kcal × 10^3)	122·1 ± 4·2	139·1 ± 8·5	103·5 ± 3·1
Weight gained (kg)	1·0 ± 0·57	2·2 ± 0·51	2·6 ± 0·16
Increase in thoracic girth (cm)	0·3 ± 1·41	3·5 ± 1·70	2·6 ± 1·33
Abdominal depot fat + epididymal fat (g)	33·6 ± 7·0	81·5 ± 5·2	38·6 ± 19·7
Lipid content of abdominal depot fat (g/100 g)	60·5 ± 10·3	80·2 ± 1·7	64·3 ± 5·3

* The values are means and standard errors of means for groups of four mature baboons, two male and two female. Differences between sexes were not significant.

The total serum lipid of the baboons fed the three diets increased during the first 2 weeks, and the increase was greatest in the animals fed sucrose; at the end of the experiment, the total serum lipid in these was significantly higher ($P < 0·01$) than in the animals fed liquid glucose or the control diet. The serum β-lipoprotein was also significantly higher ($P < 0·01$) in the baboons fed sucrose than in those fed liquid glucose, while the corresponding value in the control group was intermediate.

Although the animals fed sucrose showed trends towards higher food intake, greater weight gain and larger increase in thoracic girth than those fed liquid glucose, the differences were not statistically significant.

In the animals fed sucrose, the combined weight of abdominal and epididymal fat was significantly greater ($P < 0·01$) than in those fed either of the other diets. The abdominal depot fat from the animals fed sucrose also contained significantly more lipid ($P < 0·01$) than that from the other animals.

Small atherosclerotic plaques were found in some animals, but their frequency was not related to the diet used and the lesions were apparently of long standing.

Our initial results indicate that, compared with a high liquid glucose diet, a high sucrose diet increases the level of serum lipid, and that this increase is associated with an increase in the amount of abdominal fat deposited. If these results with primates are confirmed in tests with larger numbers they could have implications for human diets.

We thank Dr. G. A. Gresham for examining the aortae at post-mortem.

PATHOLOGY

Breast Cancer in a Tree Shrew (*Tupaia glis*)

On May 29, 1965, a female tree shrew—*Tupaia glis sordida*, according to the system of Lyon[1]—was found in a late stage of pregnancy on Tioman Island off Malaya. A nodular lesion measuring about 4 mm was present beneath the skin of the right thoracic breast near the nipple. No other lesions were found and there were no large ectoparasites. The animal was marked and released in accordance with standard procedure[2]. Three days later, the animal was found dead in a trap; the cause of death was not apparent, and the animal was well preserved and had obviously given birth since it was released. The carcass was injected with 70 per cent alcohol, and a week later placed in a strong solution of formaldehyde, and taken to the United States. On arrival it was washed in water and examined.

The skin was intact except for a reddish-grey, wrinkled, somewhat indurated area of skin surrounding the right thoracic nipple, which measured about 4 mm in greatest dimension. The nipple itself was short and retracted. Beneath the skin about 1 cm to the right of this area and a little below it was a firm nodule 3 mm in diameter, which was not freely movable. A somewhat smaller area of discoloured and indurated skin was found near and above the abdominal nipple. The thoracic and abdominal breast nipples on the left side were prominent and intact, and measured slightly more than 2 mm in length. The skin on the left side showed no lesions and felt soft.

Dissection of the skin from the thorax and abdomen on the left side revealed a layer of enlarged, lobulated, yellow breast tissue extending from the upper thorax to the inguinal region, which measured 5 mm in thickness. Dissection of the skin and underlying breast tissue from the right side was more difficult. In general, the breast tissue on this side was much thinner (less than 3 mm), and less uniformly enlarged than on the left. Breast tissue was almost wholly absent from some parts of the thoracic and abdominal region. The subcutaneous nodule near the right thoracic nipple was found to consist of poorly demarcated, firm, grey tissue. The thoracic and abdominal viscera were grossly normal in arrangement and appearance. The bicornuate uterus was enlarged, and both uterine horns were dilated, which was consistent with the recent pregnancy. The ovaries were small.

Sections of skin and underlying breast tissue from the intact left side of the thorax and abdomen showed well-preserved normal epidermis and dermis and a large amount of normal lactating mammary tissue. Much of the subcutaneous fat and breast tissue from the right side of the thorax and abdomen was replaced by an invasive malignant tumour of epithelial origin.

The subcutaneous nodule consisted of (1) glandular tumour tissue (Fig. 1*a*); (2) extensive intraductal tumour growth with distension and inflammation of ducts; (3) a small amount of normal lactating mammary tissue. The tumour showed areas of acute and chronic inflammation with oedema and fibrosis, especially around the enlarged and greatly distended ducts filled with tumour cells and debris. Many tumour cells showed large secretory vacuoles in the cytoplasm, but only in the more differentiated portions of the tumour. Small calcified concretions were scattered throughout the tumour.

Sampling of the skin from the entire right side showed that the tumour had spread from above the right thoracic nipple to a little below the abdominal nipple. Although the tumour was confined to the subcutaneous tissues and the dermis, leaving the epidermis largely intact, it had invaded lymphatic channels in the dermis and perineural spaces, compressing the nerves (Fig. 1*b*). There was an isolated intraductal papillary lesion in one section of lactating breast tissue which otherwise showed no abnormalities.

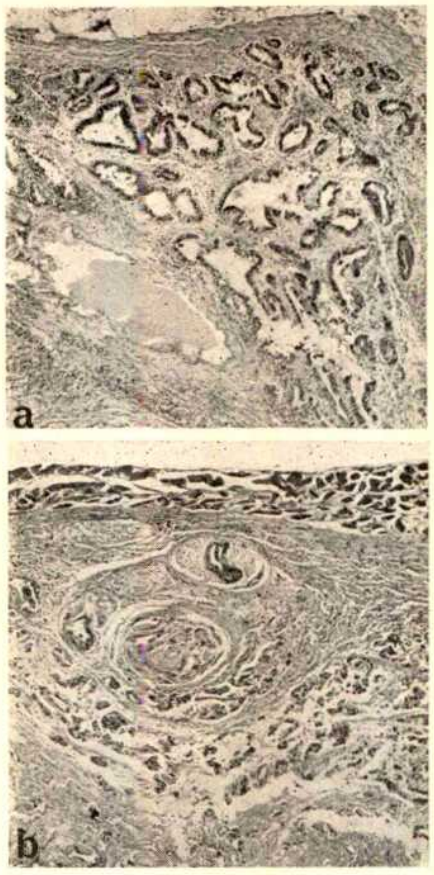

Fig. 1. Adenocarcinoma of breast (*a*) with invasion of perineural spaces compressing nerve (*e*) of a tree shrew (*Tupaia glis*). (× 50.)

A careful search was made for parasites in the tumour and in adjacent breast tissue, but none was found.

This adenocarcinoma is the only tumour which we observed during a study of tree shrews on the Malayan Peninsula over a period of 4 years. About 400 animals were observed carefully enough to ensure detection of tumours or other external abnormalities had they been present. Of these 75 per cent were adults, 55 per cent females and thirty-nine were pregnant. Although many instances of "spontaneous" benign and malignant tumours in sub-human primates have been reported, we have found no reference to neoplastic disease occurring in Tupaioidea[3].

GENERAL

Evaluation of the Queue Length Distribution for some Queues with Correlated Inputs

THE need for further progress in the analysis of queues with correlated inputs has been referred to by Kendall[1] and Lindley[2]; while systems with randomly delayed regular inputs have been studied[3,4], explicit results do not appear to be available except when the disturbances from regularity are small. Consider the case of a single server queue, with exponential service times $\mu e^{-\mu t}dt$ ($\mu^{-1} = \rho$, the traffic intensity) and an input generated by superposing independent random exponential delays $\lambda e^{-\lambda t}dt$ on a grid of scheduled time-points . . ., −1, 0, 1, 2, ... The characteristics of this system ("model A", say) are so far unsolved, but Kendall has suggested that progress might be possible if the model were modified by redistributing the arrivals randomly within each scheduled interval $(i, i + 1)$ ("model B"). Except when λ is large (the nearly regular case), model B approximates to model A. The purpose of this communication is to show, with examples, that explicit results can be obtained with this type of modified model.

Let x be the number of overdue arrivals and y the number queueing (including the one, if any, being served) at time 1^-, that is to say just before a scheduled point. Then (x) and (x, y) are each Markovian. If m and n are the corresponding values at 0^-, the number of arrivals in $[0, 1)$ is $m + 1 - x = a$, say. Assume that the distribution of these a arrivals over $[0, 1)$ depends only on the values of n and a; this defines a class of models which includes model A, model B and also, for example, model C: all a arrivals at 0^+, and model D: all a arrivals at 1^-.

For the Markov chain (x), the transition probability $p_{x|m}$ is $\binom{m+1}{x} p^{m+1-x} q^x$, ($p = 1 - e^{-\lambda}$, $q = e^{-\lambda}$), and the stationary distribution of x, ω_x say, can be readily computed from the generating function

$$\Sigma\omega_x z^x = \prod_{j=1}^{\infty} (1 - q^j + zq^j)$$

For the Markov chain (x, y), the transition probability $p_{x,y|m,n}$ is of the form $p_{x|m}\, p_{y|a,n}$, vanishes when $x > m + 1$ and also when $x + y > m + n + 1$, and equals $p_{x|m} e^{-\mu} \mu^{a+n-y}/(a + n - y)!$ when $m + 1 < x + y \leqslant m + n + 1$; thus the transition probability matrix takes the form

$$\begin{pmatrix} pN_1 & qN_0 & 0 & 0 & 0 & . & . \\ p^2N_2 & 2pqN_1 & q^2N_0 & 0 & 0 & . & . \\ p^3N_3 & 3p^2qN_2 & 3pq^2N_1 & q^3N_0 & 0 & . & . \\ . & . & . & . & . & . & . \end{pmatrix}$$

where rows are labelled by m and columns by x, each element being a sub-matrix associated with a set of transitions for fixed m, x. The sub-matrices $\mathbf{N}_a$ (in which rows are labelled by n and columns by y) are stochastic. $\mathbf{N}_0$ is the same for all input models of the class, with (n, y)th element 0 for $n < y$, $e^{-\mu}\mu^{n-y}/(n-y)!$ for $n \geqslant y > 0$, and $e^{-\mu}S_n$ for $y = 0$, where S_n denotes $\sum_{r=n}^{\infty} \mu^r/r!$. For $a \geqslant 1$, the $(a + j)$th column of $\mathbf{N}_a$ is the same as the jth column of $\mathbf{N}_0$ when $j > 1$; the distribution of probability among the first $a + 1$ columns of $\mathbf{N}_a$ depends, subject to the stochastic condition, on the particular input model (A, B, etc.). Accordingly, if the stationary distribution of x, y is denoted by c_{xy}, with $(c_{x0}, c_{x1}, \ldots) = \mathbf{c}'_x$, the probabilities c_{xy} satisfy equations of the form

$$\sum_m \binom{m+1}{x} p^{m+1-x} q^x\, \mathbf{c}'_m \mathbf{N}_{m+1-x} = \mathbf{c}'_x$$

It is advantageous to post-multiply by $\mathbf{N}_0^{-1}$, which gives

$$\sum_m \binom{m+1}{x} p^{m+1-x} q^x\, \mathbf{c}'_m (\mathbf{N}_{m+1-x}\mathbf{N}_0^{-1}) = \mathbf{c}'_x\mathbf{N}_0^{-1}, \quad \ldots \quad (1)$$

because one finds that the matrices $\mathbf{N}_a\mathbf{N}_0^{-1}$ take simple forms. $\mathbf{N}_0^{-1}$ itself is given* by $\mathbf{N}_0^{-1}(\mu) = \mathbf{N}_0(-\mu)$. Thus, in the case of model C, $\mathbf{N}_a\mathbf{N}_0^{-1} = \mathbf{U}^a$, where

$$\mathbf{U} = \begin{pmatrix} 0 & 1 & 0 & 0 & . & . \\ 0 & 0 & 1 & 0 & . & . \\ 0 & 0 & 0 & 1 & . & . \\ . & . & . & . & . & . \end{pmatrix}$$

Equations (1) can then be solved iteratively in any given numerical case, providing μ is not too near to 1. For example, when $e^{-\lambda} = 0{\cdot}5$ (that is, mean delay = 1·44 × scheduled interval) and $\mu = 2$ (that is, traffic intensity = 0·5), the stationary distribution is as follows:

x/y	0	1	2	3	4	5	6	
0	0·1657	0·0636	0·0387	0·0151	0·0044	0·0011	0·0002	0·2888
1	0·3490	0·0738	0·0302	0·0085	0·0020	0·0004	0·0001	0·4640
2	0·1803	0·0210	0·0057	0·0012	0·0003			0·2085
3	0·0334	0·0021	0·0004					0·0359
4	0·0026	0·0001						0·0027
5	0·0001							0·0001
	0·7311	0·1606	0·0750	0·0248	0·0067	0·0015	0·0003	1·0000

The known values of $\omega_x = \Sigma_y c_{xy}$ determine at the start of the calculation the effective x-range (for example, for $\lambda = 0{\cdot}1$ one would take, say, $4 \leqslant x \leqslant 16$); the effective y-range for each x is not predetermined but emerges as a by-product of the solution. Beginning with estimates such as $(\hat{c}_{x0})_1 = \omega_x$, $(\hat{c}_{xy})_1 = 0$ $(y > 0)$, one solves each of the equations (1) in appropriate order for the leading $\hat{c}_{xy}$ on the right hand side, takes $(\hat{c}_{x0})_2$ for the next cycle as $\omega_x - \Sigma_{y>0}(\hat{c}_{xy})_2$, and so on. The particular distribution tabulated here, and also the one given below for model B, have been approximately checked by means of equivalent Monte Carlo runs.

For model B, which is of particular interest, the (n, y)th element of $\mathbf{N}_a$ can be shown to be

$$\frac{e^{-\mu}\mu^{n+a-y}}{(n+a-y)!} + \left\{\frac{a!}{(a-y)!\,\mu^y} - \frac{a!}{(a-y-1)!\,\mu^{y+1}}\right\} e^{-\mu} S_{n+a+1}$$

for $y \leqslant a$, $a \geqslant 1$, whence

$$\mathbf{N}_a\mathbf{N}_0^{-1} = \begin{pmatrix} 0 \ldots 0 & -a!\,\rho^a S_{a+1} & a!\,\rho^a S_{a+1} + 1 & 0 & 0 & . & . \\ 0 \ldots 0 & -a!\,\rho^a S_{a+2} & a!\,\rho^a S_{a+2} & & 1 & 0 & . & . \\ \underbrace{0 \ldots 0}_{a-1 \text{ columns}} & -a!\,\rho^a S_{a+3} & a!\,\rho^a S_{a+3} & & 0 & 1 & . & . \\ & . & . & . & . & . & . & . \end{pmatrix}$$

The equations for the c_{xy} can be solved numerically as before. With $e^{-\lambda} = 0{\cdot}5$ and $\mu = 2$, for example, the stationary distribution for model B is as follows:

x/y	0	1	2	3	4	5	6	7	
0	0·0824	0·1026	0·0654	0·0272	0·0085	0·0022	0·0005	0·0001	0·2889
1	0·2371	0·1485	0·0571	0·0164	0·0039	0·0008	0·0002		0·4640
2	0·1450	0·0491	0·0116	0·0023	0·0004	0·0001			0·2085
3	0·0295	0·0055	0·0008	0·0001					0·0359
4	0·0024	0·0003							0·0027
5	0·0001								0·0001
	0·4965	0·3060	0·1349	0·0460	0·0128	0·0031	0·0007	0·0001	1·0001

It is interesting to note that the probability of the server being free at time 1^- is 0·4965, slightly below the overall value $1 - \rho = 0{\cdot}5$; there is a phase effect, the value of any such probability varying with the position in the time-grid at which it is measured. The phase effect is small except for large values of λ. In the extreme case of regular arrivals ($\lambda \to \infty$) re-positioned one in each grid interval according to model B, the probability of the server being free at 1^- can be shown to be

$$1 - \frac{\beta^2(e^{\mu} - 1)}{\beta e^{\mu} - 1}$$

where $e^{(\beta-1)\mu} = \beta$. When $\rho = 0{\cdot}5$ this comes to 0·4739.

Part of this research was done during the summer of 1965 while I was working at the Statistical Laboratory,

* I am indebted to the referee for pointing out that this is a consequence of the fact that $N_0(\mu) = \exp(\mu U')$.

Nature's Time-scale

PROF. MCCORMICK[1] has recently suggested that "all naturally occurring phenomena proceed according to exponential functions of time and each process in Nature conforms to its own unique time scale". The empirical equation:

$$Y = \exp(-kt^{-c})$$

is suggested as an appropriate quantitative formulation, the values of k and c depending on the process considered.

There is no doubt that an extremely diverse series of processes do indeed closely obey a law of the kind considered, so long as they occur under controlled conditions, and it is well worthwhile to direct attention again to this.

It must of course be noted that the formulation does not represent any natural phenomenon if taken literally, that is as valid for all values of t up to infinity, but must be subjected to an arbitrary cut-off at a finite value of t at the end of the experiment or when the subject dies or is thrown away, etc. This objection may fairly be regarded as trivial but even so it is scarcely justifiable to claim that such a formulation is relevant to all natural phenomena. Even if we limit ourselves, from the entire range of nature, to a two-component biological system, there are two common classes which cannot be even approximately represented by such a formula.

With changes only in quantitative properties of the components in such a system, we can illustrate the class which McCormick suggests to be universal, or either of the two quite different classes.

Suppose that we start with a few individuals of a single species of herbivore, with no natural enemies, confined to a limited area on which grows a single species of vegetation.

Case 1. Suppose that the vegetation is a continuously growing perennial type like a turf-forming grass and that the herbivore is a continuously breeding kind, with marked territorial habits, that is in which each breeding pair is able to defend an area adequate for the sustenance of itself and its offspring against other members of the species (as, for example, do grouse). The excess population unable to find unoccupied territory does not breed. Then the system will be well represented by one of McCormick's curves in which there is an initial exponential growth of the herbivore population, which later slows down as the breeding population expands to occupy the whole area available. The population will then tend to a stable equilibrium which will remain unchanged until it is disturbed from outside or until the character of one of the species changes.

Case 2. Suppose now that the herbivore exhibits no territorial behaviour, that the vegetation has a marked seasonal growth and that this seasonal growth continues for a period long compared with the breeding period of the herbivore.

Again, the early part of the curve showing the growth of the herbivore population will be closely in agreement with the early exponential part of one of McCormick's curves. As the growing season finishes, however, the herbivores may have reached numbers which cannot possibly be supported by the dormant vegetation until the next growing season; if they are reasonably efficient at finding residual vegetation they will destroy this and the entire animal population will die, a result which cannot be represented from any modification of the exponential relation already given.

Case 3. Here we will suppose a very large effect of abundance of food on the fertility of the herbivores—whether this is physiological or behavioural is unimportant—together with a maturation period long compared with the recovery rate of vegetation. The latter will be supposed to be continuously growing as in Case 1. Here again the initial rate of rise of population is normally exponential, but as the food supply begins to dwindle the reproduction rate will drop. This will not at first reduce the number of consumers, so that the food and the reproduction rate will dwindle more rapidly still until the population begins to fall as a result of starvation or old age. Eventually a minimum number of animals will be reached which the damaged vegetation can just keep alive. No reproduction occurs in this period, and presently old age will begin to remove further herbivores. The vegetation can then begin to recover and will soon reach a level at which reproduction of the herbivores becomes possible again. Because maturation is slow, however, this does not for a long time appreciably increase the consuming population, and the vegetation is able to escape from its limitation and build up to its original luxuriance.

The herbivores can now begin to expand exponentially again and, in suitable conditions, the process will be repeated indefinitely, giving a stable periodic variation in herbivore numbers of the kind known to engineers as a relaxation oscillation.

Such a periodic variation must be represented by a Fourier series and cannot be even remotely represented by McCormick's "general" equation.

In real life none of these cases will occur in so simple a form, but it would seem to me that a periodic solution of the general type of Case 3 is far more frequently found in nature than either of the other two. The conditions for such oscillations are well known to engineers; they occur whenever a change of any quantity produces effects which will tend to reverse this change but which operate after a time lag. The numerical relations determining the frequency of oscillation are given in any advanced textbook of electrical engineering.

I should like to make a final comment on the proposal for logarithmic scales of temperature or pressure. This, though undoubtedly advantageous in some ranges, is not so over the ranges commonly used. Let us write pT for temperature on a logarithmic scale by analogy with pH; suppose that we take what is now written as 1°K as our "base" where $pT = 0$ so as to avoid negative values over our main working range. Then normal human mouth temperature will be $pT = 2{\cdot}4912$ (36·9° C) while a high fever will be represented by $pT = 2{\cdot}4955$ (40° C). When the temperature falls below $pT = 2{\cdot}436$ there is danger of ice on the roads while on a hot day the temperature might reach $2{\cdot}493$ in the shade. The entire range of biological phenomena will occur between $pT = 2{\cdot}4$ and $pT = 2{\cdot}6$. This is not convenient. Such quantities as specific heat or thermal conductivity would be no longer even approximately constant. The fact is that in most of our ordinary experience, and in much of our scientific work, we are concerned with temperature differences, not ratios, and the former are not readily handled on a logarithmic scale. I would invite Prof. McCormick to rewrite Newton's law of cooling using a logarithmic temperature scale.

In the case of pressure also, there are practical inconveniences in recording small changes; Boyle's law, for example, becomes very awkward unless we also measure volumes logarithmically. Then, indeed, it becomes even simpler than the standard formulation, but it will be difficult to persuade the ordinary man that to order one unit of milk he writes 0 on the slate but to get two units he must write 0·301. Incidentally, it is incorrect

to say that a perfect vacuum has never been obtained. In any radiation-shielded experiment at very low temperatures, say 0·1°K or less, the vapour pressure even of helium is so low that there will be as many as one free molecule of gas in the cooled volume less than once a century.

The logarithmic notation, as in the case of *p*H, or of the decibel used by the electrical engineer, is valuable where very long ranges are habitually used, with only moderate accuracy required. For limited ranges and high accuracies it is not advantageous.

J. H. FREMLIN

Department of Physics,
University of Birmingham.

[1] McCormick, N. G., *Nature*, 208, 334 (1965)

PROF. FREMLIN'S criticism is based primarily on the inability of the equation, $Y = \exp(-kt^{-c})$, to describe adequately natural processes that do not have apparent sigmoidal time-course curves. Of the three hypothetical situations presented, I agree that the first would describe a typical sigmoid curve which can be generated by the basic equation. The time-course of the type of process outlined in the second case would resemble a frequency distribution function, a curve which is generated by the first derivative of the equation[1]. My colleagues and I have suggested that the equation may represent a new type of distribution function[2]. The similarities between the parameters of the equation and those of the Weibull distribution function[3] have been noted[4].

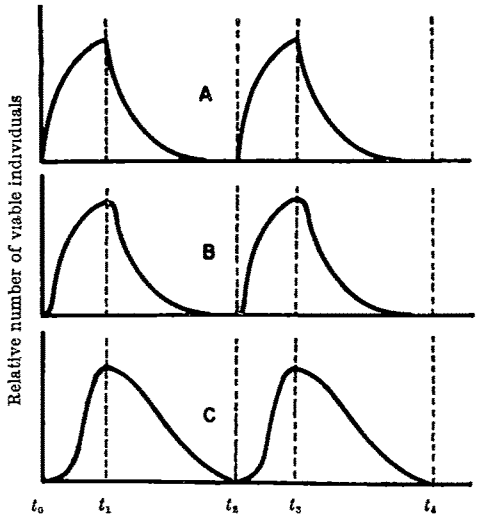

Fig. 1.

Fremlin states that the third hypothetical case gives rise to a curve resembling that known as a "relaxation oscillation", in which instance the resulting curve could not be generated by the equation. He refers to a stable periodic variation which implies to me that each cycle of growth must achieve the same maximum density before it declines into the death phase. If the curve describes a relaxation oscillation it must increase in some exponential manner to a maximum, then decrease in an exponential manner, as in Fig. 1*A*. Any process of growth as it occurs in nature will possess an induction period and the sharpness of the peak will be rounded off as in Fig. 1*B*. In this case the "relaxation oscillation" might be represented by the following series of sigmoidal growth curves and sigmoidal decay curves:

$$\int_{t_0}^{t_1} Y'_a\,dt - \int_{t_1}^{t_2} Y'_b\,dt + \int_{t_2}^{t_3} Y'_c\,dt - \int_{t_3}^{t_4} Y'_d\,dt \ldots \qquad (1)$$

where Y'_a and Y'_c are the rates of increase for the phases of growth and Y'_b and Y'_d are the rates of decline for the death phases. As an alternative, the experimental curve might better resemble a series of distribution functions as in Fig. 1*C*. This curve might be represented by the series

$$\int_{t_0}^{t_2} Y''_a\,dt + \int_{t_2}^{t_4} Y''_b\,dt \ldots \qquad (2)$$

Depending on the values of k and c for each function, either equation can generate a relaxation oscillation in which each successive wave is diminished in amplitude. By proper selection of the limits of integration the duration of each succeeding cycle can be made to increase. These properties are more likely to be found in nature than an oscillation with periods of constant amplitude and equal duration. It may be of some interest that higher order derivatives of the equation generate damped oscillation curves with cycles of decreasing amplitude and increasing duration.

A discussion of the aforementioned points is relevant to the acceptance or rejection of the proposal of exponential time scales[5]. A polemic over the issue of logarithmic scales of temperature of pressure can, however, serve no useful purpose at this time. Fremlin states in several instances that inconvenience is a major reason for not considering these scales. It is my contention that the inconveniences are not insurmountable and are far overshadowed by the possibilities of a better understanding of nature. The main point I am trying to make is the proposal that all processes in nature conform to exponential functions of time, and that the time-scale of each process is exponentially related to the time-scale of every other process. I am proposing a different kind of clock than the one our senses dictate, an inconvenient clock, perhaps, but a clock that affords a different perspective into nature's time-scale.

I would like to point out that the equation applies ideally to a process in a closed system where the time-course of the process is determined by the initial conditions. So long as no outside influence is exerted on the system after time zero (t_0), the process (Process I) flows smoothly and continuously. The instant any condition changes, Process I is terminated and a new process (Process II) comes into existence, with new initial conditions and a new time zero (τ_0). All preceding events experienced by the constituents of Process II are of no consequence because they are all incorporated into the new initial conditions. Thus Process II cannot continue to be timed in reference to the former t_0, but only with reference to the new τ_0 involving its own initial conditions.

My reply to the criticism of the statement concerning a perfect vacuum is that so long as the data must be expressed as the probability of finding a molecule within a specified volume of space at a specified time, I can agree only that the probability approaches zero as the temperature approaches absolute zero and, accordingly, the vacuum approaches a perfect vacuum.

N. G. MCCORMICK

Department of Microbiology,
School of Medicine,
University of Virginia,
Charlottesville, Virginia.

FORTHCOMING EVENTS

(Meetings marked with an asterisk are open to the public)

Sunday, September 4—Wednesday, September 7

BRITISH ASSOCIATION FOR THE ADVANCEMENT OF SCIENCE (at Nottingham)—Continuation of 128th Annual Meeting.

Sunday, September 4

At 10.45 a.m.—Official Service at St. Mary's Church. Preacher: Canon D. R. Feaver.

Monday, September 5

At 10 a.m.—Prof. J. S. Weiner: "Aspects of Human Adaptation" (Presidential Address, Section H).

At 10 a.m.—Prof. J. N. Bradley: "Shock Waves in Chemistry and Physics" (Kelvin Lecture).

At 10 a.m.—Dr. D. Noble: "How the Heart Beats" (Darwin Lecture).

At 2.30 p.m.—Prof. R. L. F. Boyd: "The Rocket Age" (Young People's Lecture).

At 8 p.m.—Dr. N. Tinbergen, F.R.S.: "Behaviour as Equipment for Survival" (Evening Discourse).

Tuesday, September 6

At 11.30 a.m.—Prof. R. J. Ball: "Economic Model Building for Control" (Lister Lecture).

At 2.30 p.m.—Prof. A. R. Gemmell: "Biology and Crime" (Young People's Lecture).

Monday, September 5—Friday, September 9

BRITISH PHARMACEUTICAL CONFERENCE (at Manchester)—103rd Annual Meeting.

Thursday, September 8

INSTITUTION OF CHEMICAL ENGINEERS (at the Geological Society, Burlington House, Piccadilly, London, W.1), at 3 p.m.—Meeting on "The Further Education of the Graduate Chemical Engineer". Chairman: Mr. F. E. Warner. Speakers: Prof. Frank Morton, Mr. H. Arthur and Mr. John Kane.

APPOINTMENTS VACANT

APPLICATIONS are invited for the following appointments on or before the dates mentioned:

LECTURER or ASSISTANT LECTURER (with good professional qualifications and experience in ophthalmic optics or in a related science) IN THE OPHTHALMIC OPTICS SECTION OF THE DEPARTMENT OF PHYSICS—The Staff Officer, The University of Aston in Birmingham, Gosta Green, Birmingham, 4, quoting Ref. 495/2 (September 9).

LECTURER (graduate in science, already with, or wishing to have, experience and research opportunities in virology, including clinical virology) IN THE DEPARTMENT OF BACTERIOLOGY—The Secretary, The University, Aberdeen (September 10).

RESEARCH FELLOW (honours graduate in physics, electronic engineering or geology) at the Tidal Institute and Observatory, to join a research project concerned with the investigation on a regional basis of tides of the solid earth and associated phenomena—The Registrar, The University, Liverpool, 3, quoting Ref. CV/207/N (September 10).

SENIOR RESEARCH ASSISTANT or TEMPORARY ASSISTANT LECTURER IN THE DEPARTMENT OF SOCIOLOGY to contribute to the development of urban sociology and the study of consumer behaviour—The Secretary, University of Edinburgh, Old College, South Bridge, Edinburgh (September 11).

EXPERIMENTAL OFFICER or SENIOR TECHNICIAN IN THE RADIATION PROTECTION SERVICE which provides health physics services for the twenty-one departments in the University in which radioactive substances or ionizing radiations are used—Dr. D. Hughes, Radiation Protection Officer, The University, Leeds, 2 (September 12).

RESEARCH ASSISTANT (with a first- or upper second-class honours degree in botany, and special interests in plant pathology and fine structure of plant cells), and a TECHNICIAN (with experience in preparation, sectioning and electron microscopy of plant material) in connexion with research on electron microscopy of infection of plants by fungi—Prof. B. K. S. Wood, Botany and Plant Technology Department, Imperial College of Science and Technology, London, S.W.7 (September 12).

EXPERIMENTAL OFFICER (with H.N.C. or university ordinary degree in science, and experienced and interested in histological techniques) IN THE DEPARTMENT OF MICROBIOLOGY—The Professor of Microbiology, The Queen's University, Belfast, Northern Ireland (September 15).

TEACHING FELLOW IN MICROBIOLOGY at Rhodes University—The Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1, or The Registrar, Rhodes University, Grahamstown, South Africa (South Africa and London, September 15).

LECTURER IN THE MECHANICAL AND ENGINEERING PROPERTIES OF MATERIALS (with particular reference to polymeric materials)—The Registrar, The College of Aeronautics, Cranfield, Bedford (September 16).

RESEARCH ASSISTANT (graduate in either science or medicine) IN THE DEPARTMENT OF SURGICAL SCIENCE to work on experimental immunotherapy of cancer, under the direction of Prof. M. F. A. Woodruff—The Secretary, Department of Surgical Science, University of Edinburgh Medical School, Teviot Place, Edinburgh (September 17).

SENIOR RESEARCH FELLOW (graduate in engineering, mathematics or physics) IN THE SCHOOL OF ENGINEERING, to work on an analytical and experimental investigation of rolling contact phenomena—The Registrar, University College of Swansea, Singleton Park, Swansea, South Wales (September 17).

SCIENTIFIC OFFICER/SENIOR SCIENTIFIC OFFICER (with a good honours degree in botany or biology and preferably postgraduate experience in ecological research) to take part in the ecological studies of the Nature Conservancy's Conservation Research Division at its Monks Wood Experimental Station, Abbots Ripton, Huntingdon—The Natural Environment Research Council (E), State House, High Holborn, London, W.C.1 (September 24).

ASSISTANT BOTANIST (man or woman graduate) at Wisley for duties which will include advisory work, dealing with queries on plant physiology, genetics and chemistry, plant identification, cataloguing and labelling and committee work—The Secretary, The Royal Horticultural Society, Vincent Square, London, S.W.1 (September 30).

CHEMIST (B.Sc. Hons.) IN THE AUCKLAND LABORATORY OF THE DEPARTMENT OF SCIENTIFIC AND INDUSTRIAL RESEARCH, to work with a small group of specialists in the field of industrial chemical research and service, including problems in plastics, waters and corrosion—The High Commissioner for New Zealand, New Zealand House, Haymarket, London, S.W.1, quoting Ref. B13/18/50/3234 (September 30).

JUNIOR DEMONSTRATOR (non-medical) (preferably with experience in some branch of endocrinology) IN THE DEPARTMENT OF PHYSIOLOGY to assist in the practical teaching of undergraduate students—Prof. A. A. Harper, The Department of Physiology, The Medical School, University of Newcastle upon Tyne, Newcastle upon Tyne, 1 (September 30).

LECTURER IN PHYSIOLOGY or BIOCHEMISTRY (with special reference to toxicology)—The Registrar (Room 39, O.R.B.), The University, Reading (September 30).

LECTURER IN THE DEPARTMENT OF PHYSICS—The Registrar, The University of Manchester Institute of Science and Technology, Sackville Street, Manchester, 1 (September 30).

LIBRARIAN to the proposed University of Bradford—The Registrar, Bradford Institute of Technology, Bradford, 7 (September 30).

ASSISTANT LECTURER (primarily interested in experimental psychology) IN PSYCHOLOGY—The Registrar, The University, Liverpool, quoting Ref. CV.216 (October 1).

ASSISTANT LECTURERS (2) in the Bland-Sutton Institute of Pathology—The Secretary, Middlesex Hospital Medical School, Mortimer Street, London, W.1 (October 1).

SECRETARY (with a degree or equivalent qualification in science or engineering and experience of administration) OF THE PHYSICS DEPARTMENT, for duties which will include responsibility for the technical staff of the Department, negotiations about research grants and detailed planning of a new building—Prof. Sir Nevill Mott, Cavendish Laboratory, University of Cambridge, Free School Lane, Cambridge (October 1).

LECTURER IN BIOCHEMISTRY at the University of Sydney, Australia—The Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (Australia and London, October 10).

DIRECTOR (medical graduate with substantial research experience) OF MEDICAL RESEARCH at the Kanematsu Memorial Institute—H. R. Beer, Chief Executive Officer, Sydney Hospital, Box 1614, G.P.O., Sydney, N.S.W., Australia (October 31).

READER IN HISTORY AND PHILOSOPHY OF SCIENCE—The Secretary-General of the Faculties, University of Cambridge, The Old Schools, Cambridge (November 16).

LECTURER/SENIOR LECTURER (with a degree in veterinary science registrable in the State of Victoria and postgraduate teaching or research experience in veterinary pathology) IN THE DEPARTMENT OF VETERINARY PARACLINICAL SCIENCE, University of Melbourne, Australia—The Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (Australia and London, November 30).

BIOCHEMIST for research on dental caries in relation to dietary factors with particular reference to carbohydrate; and a CHEMIST for research on modified flour and wheat starch and the study of potential commercial application of such products—The Director of Research, Research Association of British Flour Millers, Cereals Research Station, St. Albans, Herts.

BIOCHEMIST to collaborate in research into lipoprotein metabolism in children—The Secretary, Institute of Child Health, 30 Guilford Street, London, W.C.1, quoting Ref. CH/B.

BOTANIST (with a B.Sc. with botany as a main subject and national of, and permanently resident in, the United Kingdom or the Republic of Ireland) IN THE NATURAL CHEMOTHERAPEUTICS RESEARCH LABORATORY, KAMPALA, UGANDA, for work which will involve the identification and evaluation of local medicines for commercial exploitation—Ministry of Overseas Development, Room 404, Eland House, Stag Place, London, S.W.1, quoting Ref. No. RC205/183/030.

DEMONSTRATOR (graduate in biochemistry or chemistry) IN BIOCHEMISTRY—The Acting Registrar, University College of Wales, Aberystwyth.

ELECTRON MICROSCOPIST (with extensive experience in preparing thin sections and familiar with the maintenance and operation of the Siemens electron microscope) in the Electron Microscopy Unit for duties which will include maintenance, demonstrating the equipment to potential microscope users, assistance in the development and application of new cytochemical techniques, and possibly the supervision of other electron microscopes—The Secretary, Royal Free Hospital School of Medicine, 8 Hunter Street, London, W.C.1.

EXPERIMENTAL OFFICER (graduate in electrical or electronic engineering) for work in connexion with the University of London Inter-collegiate Research Service for Chemistry and Related Sciences and to be responsible for the running and maintenance of a Decca electron paramagnetic resonance spectrometer under the general supervision of Dr. K. D. Sales—The Registrar, Queen Mary College (University of London), Mile End Road, London, E.1.

LECTURER (honours graduate interested in general and social psychology) IN PSYCHOLOGY—The Principal, Lanchester College of Technology, Priory Street, Coventry.

MATHEMATICIANS to work on a wide range of problems arising from research into the utilization and distribution of electricity; topics include: arc physics, electro chemical reaction kinetics, solid state devices, magnetism, electrical distribution systems, heat transfer, and the application of mathematics to life science—D. C. Page, Head of Personnel Services, The Electricity Council Research Centre, Capenhurst, Chester, quoting Ref. N/29.

MEDICAL RESEARCH COUNCIL POSTDOCTORAL FELLOW IN THE DEPARTMENT OF PHYSIOLOGY—Dr. J. C. Brown, Department of Physiology, University of British Columbia, Vancouver B.C., Canada.

PHYSICIST, BASIC GRADE (honours graduate, male or female, in physics) in a newly established medical physics department serving Cornwall and South-west Devon, based in new premises at Plymouth General Hospital—The Hospital Secretary, Plymouth General Hospital, North Friary House, Greenbank Terrace, Plymouth, Devonshire.

PHYSIOLOGIST/BIOPHYSICIST to study physiological response to controlled changes in environmental conditions—D. C. Page, Head of Personnel Services, The Electricity Council Research Centre, Capenhurst, Chester, quoting Ref. N/28.

POSTDOCTORAL FELLOW IN THE DEPARTMENT OF CHEMISTRY for work, supported by the S.R.C., on the photochemistry of aromatic compounds—Prof. D. Bryce-Smith, Department of Chemistry, University of Reading, Whiteknights Park, Reading.

RESEARCH ASSISTANT (graduate in engineering, mathematics, physics or geology, with research experience, preferably in materials science, applied mechanics, structural or engineering geology) to undertake original work on the engineering properties of rocks, the mechanics of rock fracture, the determination of stress and strain in rocks in situ, and the stability of rock slopes and excavations—The Registrar, The University, Sheffield, 10.

RESEARCH ASSISTANT (graduate in metallurgy, chemical engineering or allied fields with previous research experience) IN THE JOHN PERCY RESEARCH GROUP IN PROCESS METALLURGY, to assist in the administration of the research group and to conduct research on his own account (which could lead to a higher degree) in the field of high temperature process engineering applied to metallurgy—Prof. F. D. Richardson, Imperial College of Science and Technology, London, S.W.7.

RESEARCH ASSISTANT (with a university degree in biochemistry, zoology or a related subject) to study aspects of the physiology and biochemistry of less complex nervous systems of lower animals—Dr. G. A. Cottrell, Gatty Marine Laboratory, University of St. Andrews, St. Andrews, Fife, Scotland.

RESEARCH FELLOW (with a postgraduate qualification or experience in chemistry, biochemistry, and the chemistry and technology of adhesives) in DENTAL MATERIALS to participate in a broad programme of work on the development of adhesive dental filling materials under the immediate direction of Dr. D. C. Smith—Prof. E. Matthews, Department of Prosthetic Dentistry, Turner Dental School, The University, Manchester, 15.

RESEARCH OFFICER (graduate, pass or honours, in chemistry, biochemistry or any related field, and preferably some postgraduate laboratory experience) IN THE DEPARTMENT OF BIOCHEMISTRY AND AGRICULTURAL BIOCHEMISTRY, for duties which will include administrative supervision of the day-to-day running of the modern research and teaching laboratories—The Acting Registrar, University College of Wales, Aberystwyth.

SENIOR BACTERIOLOGICAL TECHNICIAN (A.I.M.L.T. or equivalent) IN THE PATHOLOGY LABORATORY—The Establishments Officer, Zoological Society of London, Regent's Park, London, N.W.1.

YOUNG POSTGRADUATE PHYSICISTS, MATERIAL SCIENTISTS, ELECTRICAL ENGINEERS, and MECHANICAL ENGINEERS to work on a new approach to the use of conducting, dielectric, and magnetic materials (also materials with compound properties) in such applications as: cabling, wiring, switching (at distribution, industrial and domestic voltages), heat transfer, and electrical machines—D. C. Page, Head of Personnel Services, The Electricity Council Research Centre, Capenhurst, near Chester, quoting Ref. N/35.

UNIVERSITIES UNDER PRESSURE

THE academic year now beginning in Britain is likely to be difficult for the universities, and not merely because there will be some who expect that the dons of Oxford will have spent at least some of the long vacation following their Vice-Chancellor's advice and reading the report of the Franks Commission so as to decide how—if at all—to respond to it. This is also the year in which the level of spending for the new quinquennium will have to be fixed, that in which research budgets will feel the first real pressures of financial restraint, and the year in which the British Government's long flirtation with what is called technology may crystallize into a frankly hostile public attitude towards institutions which are, in the last resort, cheerfully academic in their convictions and intentions. There is, in other words, a danger that, a year from now, British universities will be diminished in freedom, impoverished and robbed of their present pride of place at the apex of the British educational pyramid. As yet, there is no sign that they will lift more than a gentle little finger in their own defence.

Perhaps the most serious difficulty is the uncertainty which has grown up, in the past three years, about the real function of universities on the British pattern. Curious though it may seem, the Robbins Report, which should have helped to define a sense of purpose for the universities, has instead helped to confuse the several issues now crying out for solution. Robbins implied, and everybody seems to agree, that a substantially larger fraction of the British population than at present deserves some form of higher education. But how is this to be accomplished ? Robbins implied, and the universities joyfully agreed, that more universities on the old pattern would be the best way of doing this. Only recently has it become plain that the Robbins solution may not have been the best way of meeting the need which Robbins cogently defined. In particular, it is probably a needlessly expensive solution.
